In gout the blood contains an excess of uric acid. This was first shown by A. B. Garrod by his "thread test." This consists in placing 2 drachms of serum obtained from a blister in a shallow watch glass, adding 10 or 12 drops of acetic acid, placing in the serum three or four threads, and setting it aside for thirty or forty hours at the ordinary temperature. At the end of this time, if the threads be examined under the microscope, crystals of uric acid will be found to have formed upon them. The blood of a normal man contains up to 3 milligrammes per cent. Before an attack of gout the value is 4 to 6 milligrammes per cent. But, in spite of this high figure, the amount of uric acid excreted in the urine is below normal. Further, if a gouty person is given purins in the food there is great delay in their excretion in the urine. This points to the failure of the excretory power of the kidney as being responsible for the high uric acid in the blood. An attack of gout is associated with a sudden rise in the excretion of uric acid in the urine, which reaches its maximum on the second or third day of the attack. At the same time uratic deposits are laid down in the joints and other places. The uric acid in the blood falls. Cinchophen (diphenyl-quinolinetetracarboxylic acid) has been found to ward off attacks of gout; and it does so by increasing the uric acid excretion in the urine, and at the same time the uric acid in the blood and tissues falls (Folin). It also facilitates the excretion of uric acid if purin foods are given to a gouty person.

It must be remembered that the uric acid of the blood may be increased in diseases, such as leukæmia and severe nephritis, in which gouty attacks are absent, so that gout cannot be due merely to this cause; there must be an additional factor.

The acute articular inflammations of gout are attributed to irritation by the crystalline deposit of sodium biurate, which is found in the tissues; and possibly the visceral attacks are due to a deposition, at least temporary, of the same biurate crystals.

Symptoms. *The Gouty Attack.* In the majority of persons gout first shows itself by an attack of acute inflammation in the metatarso-phalangeal joint of one great toe. Various premonitory symptoms are noted in different cases: in some there may be an unusual feeling of health or exhilaration; but more often there are the following: mental depression; disturbed sleep; odd sensations, itching, or cramps in the limbs; tinnitus aurium; salivation, gastralgia, vomiting, or flatulence; alterations in the quantity and colour of the urine, which is mostly scanty and deposits urates. These symptoms may have been troublesome for a day or two, when the patient is awakened, commonly about two o'clock in the morning, with pain in the great toe. The pain becomes

worse and worse, and the patient finds it impossible to get ease. At the same time there may be a little chill, or even a rigor, and some fever. After some hours of excruciating pain this at length abates, and the patient may fall off to sleep; when he awakes again he finds the affected joint red and swollen. It is exquisitely tender; the skin is tense and shining, and if it can be touched, pits slightly on pressure. The veins around it are slightly distended. During the day the patient may be free from severe pain, but towards evening there is a recurrence of all the early symptoms—that is, of severe pain and some febrile reaction—which remit towards morning, to return again the following night. The joint continues swollen, and the swelling extends in the cutaneous tissues some distance up the foot; the colour is a dull, dusky red. When at length the inflammation subsides, which it does in from five to ten or fourteen days, the skin desquamates in large thick flakes, and gradually assumes its normal colour. In exceptional cases one or two toe-nails may be shed; on the other hand, in mild attacks desquamation does not occur.

The general condition of the patient is one of slight febrile reaction, with more or less gastric disturbance. The temperature is not much raised; the thermometer may reach 101° , but is rarely so high as 102° , and then only for a short time. The tongue is thickly furred, and the patient has no appetite, but much thirst, nausea, and sense of distension at the epigastrium, and is constipated. Phlebitis with thrombosis of veins is not an uncommon accompaniment of the acute attack, and uræmia may also occur if the kidneys are diseased, and there is usually a considerable polymorphonuclear leucocytosis.

When an attack of gout is at an end, the patient often feels better than he has done for a long time before; and he is, as a rule, free from any reminder of his condition for a period of several months, or even two, three, or more years. His second attack may be in the same joint as the first, an almost exact reproduction of it; or it may occur in the opposite foot, or in one ankle, or in the wrist or hand. A third attack often comes at a somewhat shorter interval than that between the first and second, and the periods of repose diminish in length as time goes on. Ultimately a great many joints have been at one or other time affected, and with repeated attacks they undergo changes which result in considerable deformity, so that the old gouty subject becomes crippled in somewhat the same way as the sufferer from rheumatoid arthritis.

When the disease has reached this stage it is in reality a *chronic gout*. If the small joints of the toes and fingers are often first affected, ultimately all the joints of the extremities may become the seat of gouty deposit, the shoulder and the hip less frequently. In the hand the joints are enlarged, are more or less fixed in different positions of flexion or extension, and in severe cases there is deviation of the fingers to the ulnar side of the hand. Similarly the foot may be fixed in a condition of talipes, or the knee or elbow in a flexed position. The swelling about the joints is often assisted by the existence of white deposits called *tophi*, which at first lie close under a thin shining skin, with dilated venules. But subsequently the skin may yield, and the creamy or chalk-like deposit may escape in small quantities at a time; or, more rarely, suppuration takes place around the deposit, and leads to its more rapid elimination. These tophi are not confined to the affected joints; they are seen under the skin of the fingers adjacent, in the bursæ (for instance, over the olecranon), in the tendons, and with considerable frequency in the cartilage of the helix of the ear. If the creamy juice from one of these deposits be examined under the microscope, it will be found to consist of innumerable minute acicular crystals, which are composed mostly of sodium biurate, with a small proportion of calcium urate or phosphate, and sodium chloride.

Gout sometimes occurs in the form of subacute or even chronic arthritis in two or more joints without any preceding typical acute attack in the great toe or hand. There is often a general resemblance to the polyarthritis of acute rheumatism.

Again, a high blood uric acid, presumably of gouty origin, is found in certain cases of typical rheumatoid arthritis.

Under the heading *irregular gout* are grouped certain disturbances which are apt to occur in gouty persons, but which have nothing really to do with the disease itself. They are gastric and intestinal catarrh, bronchitis, conjunctivitis, iritis, gouty urethritis (which is, according to Ebstein, a prostatorrhœa), neuritis, cirrhosis of the liver, and chronic eczema.

Diagnosis. The typical gouty attack occurring at night in the great toe can scarcely be confounded with anything else. It is distinguished from *acute rheumatism* by the dark red, shiny, tense swelling of one joint, the absence of general sweating, and the slight constitutional disturbance. Later illnesses implicating many joints show a closer resemblance. There is generally a history of many previous invasions of single joints, and less fever or sweating than in rheumatism; but the condition of the joints themselves cannot be relied upon as it can in early attacks. The swelling and redness of the back of the hand in gout may be such as closely to resemble *abscess*, but fluctuation can scarcely be obtained, and the history will mostly protect against errors. *Pyæmia* may be suggested by multiple gout, but rigors would be more severe, and the general disturbance more intense. In all cases the ears should be carefully examined for tophi, and, if necessary, microscopic examination of part of the tophus should be made to see if sodium biurate crystals are present, or the murexide test may be employed. In cases of doubt the uric acid in the blood may be estimated by Folin's method. A low value excludes gout, but it does not follow that if the value is high gout is necessarily present.

Radiographic examination of the chronically affected joints may be of value. Since sodium urate is not opaque to X-rays, clear areas in the neighbourhood of the joints may be seen. They have sharply defined edges, as if punched out, and are often round, varying in size up to that of a sixpence. Small pot-holes may be seen in the articular surface. The structure of the bone may appear altered, the striæ becoming irregular, and the shape of the bone may be deformed. This is ascribed to the irritation produced by the uric acid. Finger-like projections or exostoses may be seen projecting from the shaft (*see* Plate 44).

Prognosis. Gout once declared is likely to be repeated unless the conditions, dietetic or otherwise, which have led to it are altered. Acquired late in life, and properly treated, it may not materially shorten life; the associated arteriosclerosis and primary contracted kidney may be serious.

Prevention. The quantity of food taken should always be moderate. Many patients are too fat, so that a loss of weight will be an advantage. Restriction of both protein and carbohydrate foods is generally regarded as beneficial. But, most important of all, a diet containing a minimum of purin bodies should be chosen, since an attack of gout may be precipitated by such food. The foods which contain but little purins are milk, eggs, butter, cheese, fat, white bread, rice, sago, fruits, cabbage, lettuce, cauliflower, and potatoes. The foods which contain purins in quantity and so should be avoided are cocoa, chocolate, barley, oatmeal, flesh foods, including the lean of bacon and ham and most organs. Some of these foods also contain large amounts of oxalates (*see* p. 508) and so should be avoided; this also applies to potatoes. When it is not desired to cut the purins down to the minimum the following articles, containing moderate amounts of purins, may be taken; fat bacon, mutton cutlet, roast pork, tongue, stewed tripe, brains, chestnuts, asparagus, caviare, peas, oatmeal, beans, Brussels sprouts, lentils, radishes, spinach, sorrel, raspberries, rhubarb. Personal peculiarities may have to be consulted, so that indigestion is avoided, and with this proviso fat may be taken in moderation. Alcohol in any form is best avoided by those with a tendency to gout; a light white wine is the least harmful, or a small quantity of good brandy or whisky well diluted. As in diabetes, saccharin may be usefully employed for sweetening. Alkaline and saline waters

are of service, and more still, residence at the spas, where the influence of the waters is combined with a regulated diet, fresh air, and pleasant surroundings.

Cinchophen (trade names, atophan, agotan, phenoquin, and quinophan), described above, is the most valuable drug for preventing attacks of gout. It is given in 15-grain doses three times a day after meals for three days of each week. If there is gastric irritation, sodium bicarbonate, 15 grains, may be given simultaneously. The diet should contain plenty of carbohydrates. Cinchophen poisoning is now well known and the symptoms resemble closely those of poisoning by arsenobenzol (*q.v.*); toxic jaundice from acute necrosis of the liver may be imitated, and is the commonest, but all the "early toxic effects" may be imitated, apart from encephalitis, and there may be transient albuminuria (12, 13). Salicylates and sodium benzoate act similarly in increasing the excretion of uric acid in the urine. The bowels should also be kept free.

Treatment. In acute gout the affected foot should be kept raised, and supported on a chair or couch, if the patient is not in bed. It should be wrapped in cotton wool, and in severe cases some anodyne application, such as belladonna liniment, tincture of aconite, tincture of opium, or a lotion of atropine and morphia, may be previously applied sprinkled on lint, and some oiled silk or thin gutta-percha laid over all. Leeches, hot poultices, and ice applications are to be avoided. The diet must be at once restricted in younger patients to milk and farinaceous foods, but in older persons and those broken down by previous attacks it may be more liberal, but still mostly fluid and easily digestible. Alcohol should, if possible, be entirely withheld. Medicinally colchicum has a decided effect in most cases. It may be given as wine or tincture in doses of 15 to 25 minims every six or four hours, in combination with bicarbonate or citrate of potassium, or citrate of lithium. Cinchophen is useless in relieving the inflamed joint. The bowels should be kept active with calomel. If pain is very severe, morphia may be given by subcutaneous injection or internally.

HYPERTROPHIC PULMONARY OSTEO-ARTHROPATHY

"Clubbing" of the fingers is the earliest stage of this disease. The terminal digit is swollen and globular; the nail is enlarged and more convex than usual. The soft parts may be involved alone, but the phalanx is often broad and thick. In fully developed hypertrophic pulmonary osteo-arthritis the clubbing of the fingers is associated with enlargement of the bones of the extremities, particularly those of the hands and feet, and the distal ends of the long bones. There may be effusion into the joints, preceded by stiffness.

"Clubbing" occurs in two groups of cases: (1) Among people who live at great altitudes, *i.e.* the Andes (11), and in other cases of prolonged oxygen deficiency, such as chronic pulmonary disease, *e.g.* fibroid lung, phthisis, empyema and bronchiectasis, but also in mediastinal new growths, in compression of the subclavian vein by aneurysm, when unilateral clubbing has been found, in methæmoglobinæmia or sulphæmoglobinæmia, and in congenital heart disease and, rarely, acquired heart disease. (2) In this group are included a varied assortment of cases, cirrhosis of the liver, infective endocarditis, carcinoma of œsophagus, pyloric stenosis, etc. Clubbing has disappeared with relief of the primary cause. Pathological and skiagraphic observations show that in developed pulmonary osteo-arthritis there is a thin deposit of new bone under the periosteum of the long bones, and especially of the lower thirds of the radius, ulna, tibia, fibula, metacarpals, metatarsals, and proximal and middle phalanges of the hands and feet. The deposit is such as to fill up the concavity between the proximal and distal ends of the bone, and to make, for instance, in the case of a metacarpal, the middle thicker than the ends. Sometimes the joints (wrist, ankles and interphalangeal joints) contain fluid, and the synovial membrane is

thickened. In clubbing of the fingers and toes the primary change is œdema of the tissue between the nail and the phalanx, which separates the connective tissue fibrils from one another (10). In later stages this is replaced by fat and fibrous tissue. In early cases, after compressing the sides of the fingers for some little time, a boggy feeling is experienced on compressing the base of the nail, as if it was lying on thick fluid. Two factors probably play a part in the production of the œdema—desaturation of the arterial blood with oxygen and peripheral stasis. The clubbing in the second group of cases can hardly be explained in this way.

ACHONDROPLASIA

This is a congenital disease of the bones and cartilages, which results in permanent stunting of growth and other deformities. No demonstrable change has been found in the endocrine glands. Its hereditary character—it sometimes appears after skipping a generation—is more in favour of an inherited tissue defect. At birth the limbs, especially in their upper halves, are noticed to be abnormally short. The child may be of full weight, but growth is slow, the limbs continue to be short, and the stature is consequently small, though the vertebral column is of normal length. There is a projection of the buttocks which gives the appearance of lordosis and a waddling gait. The head is generally large, somewhat like a rachitic head, with a prominent forehead, but a depressed bridge of the nose. The limbs often show transverse furrows, as if the soft parts were too long for the bones. The hands present a characteristic deformity in that the index and middle fingers diverge from the ring and little fingers when the hand is open (*trident hand*). The deformities are due to defects in ossification of the cartilages of the long bones and of the innominate bones, together with a premature synostosis of the bones of the basis cranii. The cranial bones which are formed in membrane are normally developed, as well as the bones which remain cartilaginous till a late period of foetal life, viz., the sternum, patella, carpal and tarsal bones, and the costal cartilages. The thyroid is normal; and the subjects of the disease have a good intelligence, and are muscularly and sexually well developed. The disease does not usually tend to shorten life.

The changes occurring in the cartilages are of three types: (1) hypoplastic, with diminution of the cells; (2) hyperplastic, with excessive proliferation and enlargement of epiphyses; (3) softening, with defective columnar arrangement of the cells and increased vascularity. There is no abnormality of the calcium metabolism.

No treatment is of any avail.

OSTEOGENESIS IMPERFECTA

As the name implies, there is in this rare condition deficient ossification of the bones, with consequent undue fragility, especially shown in the long bones; and there is an abnormal formation of the skull, which is typical of the disease. The shafts of the long bones are curved and tortuous, and there is some shortening, which is more marked in the proximal halves of the limbs. Fractures, relatively painless, take place with great facility both in the ribs and in the limbs; the bones may unite again under a callus which is thrown out in a circular form. In the skull there is a persistent wide frontal suture, continuous with a large anterior fontanelle; and the posterior fontanelle remains also large. The bones are thin and yield to pressure, and instead of forming in each case a single bone, they present a mosaic of small irregular separate pieces of bone. In the lateral region the skull may be still unossified, and this leads to a characteristic bulging in the temporal region just above the ear, the concha of which is pushed outwards by it. The orbits are oval with the long axis vertical, and during life the eyeballs are turned downwards so as to produce some resemblance

to the condition seen in chronic hydrocephalus. Congenital, infantile and late forms are described. There is a very marked hereditary tendency. The condition is often associated with blue sclerotics (14). In the congenital form, there is frequently evidence of intra-uterine fractures which have produced deformities; few of these cases survive more than a few days.

There is a defective proliferation of the osteoblasts and calcium retention is below normal. **Treatment** should be directed to the prevention of injuries. Large doses of calcium gluconate and of vitamin D appear to be useful.

OSTEITIS DEFORMANS

(Paget's Disease)

The ætiology of this disease is unknown. Perhaps the most likely suggestion is that it is due to some defect of internal secretion; but syphilis has been considered a cause. It affects both sexes about equally, and is observed in the latter half of life.

Morbid Anatomy. The long bones of the limbs are often attacked in the early stages of the disease. They become thicker. There is an increase in the size of the marrow cavity. At the same time the compact bone becomes looser in texture and more spongy and much thicker than normal. The consequence is that the bones are light, even though they are large. The bones of the lower limb bend under the weight of the body. Similar thickening and porosity are noticed in the bones of the skull. There is kyphosis of the spine. The bones of the face, hands, feet and pelvis and the clavicles and ribs may show similar changes in slight degree. Arteriosclerosis and myocardial degeneration are often present.

Symptoms. The onset is insidious. The patient complains of pain and tenderness in the affected parts. His legs may become gradually bowed and his back bent. The increase in the size of the skull is noticed because he finds that he must wear a larger hat. Often the disease begins in one limb, and the corresponding limb on the opposite side is affected subsequently. In the later stages the patient's attitude is characteristic, with bent back, bowed legs, and large head projecting forwards. He can only waddle along with the help of a stick. The disease is slowly progressive, but does not shorten life, except that sometimes sarcoma develops in the affected bones. The bones are not liable to fracture. The blood phosphatase is increased but the calcium and phosphorus are normal.

Diagnosis. The disease must be distinguished from *acromegaly*, in which the soft parts are affected as well as the bones; *osteoarthritis*, in which the joints are affected, but not the shafts of the bones; *osteomalacia*, in which the bones are soft and liable to fracture; and *syphilis*, in which there is no general enlargement of the skull. The history of the disease and the Wassermann reaction will also help. The X-ray appearances are very characteristic (see Plate 45).

Treatment. This is symptomatic. If the Wassermann reaction is positive, anti-syphilitic measures should be adopted.

DISEASES DUE TO CERTAIN DEFICIENCIES IN DIET

ACCESSORY FOOD FACTORS

(*Vitamins*)

THE growth of the young animal depends on two sets of factors : (1) those that are inherent in the organism and are influenced by heredity ; (2) those factors in the environment that exert an influence on the organism from without. Food is the most important of these. Till recently it has usually been considered sufficient to calculate the diet solely on the energy requirements of the individual, while a protein ration was allowed more than sufficient to cover the loss by wastage of the tissues and the amount required for the formation of new tissue in the growing organism. Human experience with scurvy through many centuries has shown that something else is wanted, and we find Bachstrom writing in 1734, " This evil " (scurvy) " is solely owing to a total abstinence from fresh vegetable food and greens, which is alone the true primary cause of the disease. . . . Recent vegetables are found alone effectual to preserve the body from this malady and most speedily to cure it, even in a few days, when the case is not rendered desperate by the patient's being dropsical or consumptive." The general principle that it is impossible to keep animals alive on a diet of purified proteins, fats and carbohydrates with the necessary inorganic salts was enunciated by Hopkins (1906). The special substances that must be present in the diet are called *accessory food factors* or *vitamins*.

Fat-soluble A. Butter, cream, cow's milk, cod-liver oil and other fish oils, and egg yolk provide the most abundant sources of the vitamin. It is also present in the green leaves of plants, *e.g.* green vegetables, and the embryos of certain seeds. In fact, it may be identical with the yellow colouring matter of plants known as carotene. It is completely absent from certain vegetable fats and oils, such as olive oil, cotton-seed oil, cocoa butter, linseed oil, and also lard (specially prepared pig fat), although bacon, mutton, and beef fat contain plenty of it. It is completely destroyed when oils are " hardened " by the action of hydrogen—a process widely employed in the preparation of edible fats ; but it can stand being heated to 100° C. for an hour or two. Its presence in milk fat is in part dependent on a good supply of this substance in the food of the cow, and this is satisfied when there is plenty of green food available. In the absence of this vitamin from the diet infections readily occur, especially in the alimentary and genito-urinary tract often causing stone in the bladder, in the nasal sinuses and middle ear and round the base of the tongue, while in animals disease of the nervous system has been found. There is also absence of adipose tissue, general visceral atrophy, xerophthalmia (1), and night blindness (*hemeralopia*). The vitamin aids the growth of the soft tissues round the teeth.

Water-soluble B. This is really a group of vitamins of which vitamin B₁, which is the antineuritic or anti-beri-beri factor, and vitamin B₂, which prevents pellagra, are of clinical importance. Both vitamins occur largely together. The richest supply is the germ of rice and wheat, but the outer covering of the grain which forms bran and the *aleurone* layer just beneath it also contain the substance. Egg yolk, ox liver, yeast, and pulses contain plenty of it. A commercial prepara-

tion of yeast called *Marmite*, used for soups, is a convenient source of the substance. B_1 is only very slowly destroyed by being kept at 100° C., but much more quickly at 120° C. Hence no serious loss of the substance need be feared in the baking of bread or biscuits; on the other hand, tinned foods are to be regarded as quite free from it. B_2 is much more heat stable. When rice is "polished," the germ and the whole of the external covering of the grain (pericarp) are removed, and so the whole of the antineuritic factor is lost. When young rats are fed on "polished" rice growth stops immediately, and inco-ordination of the back legs occurs, so that the animal can no longer walk about. Pigeons also develop a polyneuritis, and this is regarded as the same disease as beri-beri. When severe symptoms have been produced experimentally they can be rapidly cured, sometimes in a few hours, by giving adequate amounts of the antineuritic factor. There is also evidence that lack of vitamin B_2 causes atrophy of the lymphoid tissues of the alimentary canal with stasis and dilatation and anæmia.

Vitamin C (*antiscorbutic*). This water soluble vitamin has now been prepared in the pure state, as *ascorbic acid*. Its richest source is paprika; but raw cabbage leaves, raw swede juice, fresh lemon and orange juice contain plenty; other substances, such as carrots, beetroot, potatoes, onions, grapes, apples, milk and fresh meat, contain comparatively small amounts, while flour, eggs and dried pulses contain none at all. However, if dried pulses, like lentils, peas and beans, are soaked in water and allowed to begin germination for two or three days, they acquire antiscorbutic properties. The vitamin is very sensitive to drying and to high temperature. Dried foodstuffs will not prevent scurvy, and cabbage loses 90 per cent. of its power when boiled in water for an hour, and the loss occurs more quickly still if alkali is present. Hence vegetables should not be cooked for longer than twenty minutes, and soda should not be added. Tablets of dried lemon juice, made up with sugar and tragacanth, retain activity for a year if kept cool.

Vitamin D (*antirachitic*). Vitamin D is fat soluble and occurs in cod-liver oil and halibut oil associated with fat-soluble A; cow's milk, which is rich in fat soluble A, is poor in vitamin D, but owing to the high calcium content milk has powerful antirachitic properties. It has been found that certain *sterols* (especially ergosterol, which occurs in ergot, yeast, etc., and phytosterol, which occurs in wheat and vegetables) after they have been irradiated with ultra-violet light, develop antirachitic properties; the pure vitamin C—*calciferol*—is prepared from irradiated ergosterol. The essential sterol probably occurs normally in the skin, and vitamin D is formed when the child, mother or the cow is exposed to sunlight; hence the value of sun-bathing.

Vitamin E is fat soluble; it has been found necessary for reproduction in rats and mice.

BERI-BERI

(*Kakke, Polyneuritis endemica, Hydrops asthmaticus*)

This is an endemic disease characterised typically by neuritis of the peripheral nerves and vagus resulting in varying degrees of paralysis, anæsthesia, cardiac dilatation and dropsy. It is due to the absence of vitamin B_1 in the diet. Several different clinical types are encountered.

Ætiology. It has been observed chiefly amongst the rice-eating populations in Japan, China, Malaya and the Philippines, but it may occur anywhere when a diet consisting chiefly of cereals is eaten provided the germ and external covering have been removed in their preparation. In whole rice, for example, the husk, pericarp and germ are rich in vitamin B as well as in protein, fat and phosphorus, and during the process of milling these are all removed leaving the residual white, polished rice poor in these constituents. Beri-beri has not infrequently

been encountered amongst sailors on sailing-ships where biscuits made from white flour and tinned food are largely eaten. It has also been recorded in Newfoundland and Labrador, where the population subsist largely on white bread throughout the winter and summer months. During the siege of Kut a remarkable outbreak of the disease took place amongst the British troops when they were subsisting chiefly on wheaten flour, but disappeared when they were compelled to eat barley flour, or *attar*, which is a coarsely ground whole-wheat flour used by the Indian troops. The British troops escaped this owing to their large ration of horse flesh which would not be eaten by the Indian troops. White bread, of course, is largely eaten in England, but here there is sufficient of the accessory factor in the rest of the diet to prevent the onset of the disease. It is noteworthy that exercise lessens the tendency to develop beri-beri (4).

Pathology. In addition to the œdema and anasarca seen during life, ecchymoses under the serous membranes, in the muscles and in the sheaths of the nerves may be found. Dilatation and hypertrophy especially involving the right side of the heart occur, also œdema and fatty degeneration of its muscular walls. The lungs are often engorged and œdematous and the liver and kidneys congested. Wallerian degeneration of the peripheral nerves occurs and often axonal degeneration as well, while there is a cellular infiltration of the endoneurium and perineurium. The vagus and sympathetic nerves may also undergo degenerative changes as well as the anterior horn cells and the nuclear connections of the vagus.

It has been suggested that (5) the swelling of the heart muscle is due to imbibition of fluid which diminishes its contractility without altering the mechanism of its beat as shown by the electro-cardiograph; excessive imbibition also occurs in the skeletal muscles, the nerves and certain glands and this process is held by some to be responsible for both the symptoms and subsequent atrophy which ensues.

Symptoms. The disease takes 80 to 90 days to develop on a diet of "polished rice," and the signs and symptoms, for the most part, are those of multiple neuritis (p. 651), to which there may be superadded certain cardiac features including dyspnœa, œdema of the legs and anasarca. The course is generally afebrile except possibly in its early stages, and it may be accompanied by gastrointestinal symptoms like epigastric discomfort, nausea and vomiting. Several different clinical types are encountered :—

(1) Mild ambulatory cases with paræsthesias, patchy anæsthesia and diminished tendon reflexes; on an appropriate diet the patients readily recover.

(2) Ordinary beri-beri of which there are two types: (a) wet; (b) dry. The onset which is generally insidious but may be almost sudden is characterised by heaviness, weakness and numbness in the limbs associated with pain in the calves and a general state of languor. In the *dry* form, as the disease develops, there are loss of power and muscular atrophy beginning in the extensors on the front of the leg and subsequently affecting the other muscles and those of the thigh; later the extensors of the hand, the biceps and sometimes the abdominal muscles, the diaphragm and the intercostals become implicated. High steppage gait and wrist drop often result. Early weakness of the legs may be revealed by the "squatting" test. To elicit this a squatting position is assumed with the knees separated and the buttocks a few inches from the floor. The patient with beri-beri finds himself unable to raise his body from this position and generally attempts to use his hands on his thighs just like the case with pseudo-hypertrophic paralysis. The knee jerks, which are hypersensitive at first, are soon lost and later the Achilles jerk and other deep reflexes disappear. Anæsthesia generally appears first over the skin of the tibia and subsequently extends to other parts of the limbs and trunks. Tenderness of the muscles, especially those of the calves, as well as painful cramps occur just as in multiple peripheral neuritis from other causes, and laryngeal paralysis with difficulty in swallowing may

also supervene. Cardiac irritability is not infrequent, and at any time the *wet* form may develop. The *wet* type is always associated with some evidence of peripheral nerve involvement to which are added various grades of subcutaneous œdema at first involving the tibiæ and later extending elsewhere. General dropsy with effusions into the pleural, peritoneal and pericardial cavities may supervene. Dyspnœa and tachycardia with a rapid, low tension pulse ensue; clinically, the right heart is dilated and there are systolic murmurs associated with a loud and reduplicated pulmonary second sound. Embryocardia is not uncommon. The urine contains little if any albumin and is free from casts.

(3) Acute cardiac type: this may develop in the course of "wet" or "dry" beri-beri or start suddenly without prodromal features. Generally there are a sense of depression, epigastric pain and nausea followed by palpitation, præcordial pain, dyspnœa and signs of congestive failure with engorged cervical veins, cyanosis, pulmonary congestion, tender enlarged liver, subcutaneous œdema and general dropsy. Aphonia and paralysis of the diaphragm may ensue and death supervenes within a few hours to a few days.

(4) Infantile beri-beri, which may assume either acute or chronic forms, occurs in Japan and the Philippine Islands in breast-fed infants whose mothers are afflicted with latent or active beri-beri. Gastro-intestinal symptoms with nausea, vomiting, diarrhœa or constipation are common, in addition to cardiac features. The administration of extract of rice polishings plus the substitution of artificial for breast feeding generally results in cure.

Diagnosis. The nature of the diet and the occurrence of multiple cases of peripheral neuritis should arouse suspicion of beri-beri, especially amongst Orientals. *Wet* beri-beri has to be differentiated from nephritis, ankylostomiasis and cardiac failure, and the *dry* form from alcoholic and arsenical neuritis and other nervous diseases.

Prognosis. The more usual case lasts from one month to a year or more and recovery is often very slow in spite of appropriate dietetic treatment. The danger lies in rapid cardiac failure, and fatal exhaustion sometimes follows vomiting. Vedder, in 1913, estimated the average mortality to be 5 per cent., but in some of the recorded epidemics it has been much higher.

Treatment. It is important where tinned foods, polished rice and white bread are largely eaten to reinforce the diet with eggs, yeast, or Marmite, which have a high vitamin B content, or to substitute under-milled rice and whole wheat flour.

Once the disease has developed the patient should be put to bed and rigidly kept there; small feeds are at first given every two hours consisting of a dry diet low in carbohydrate and containing eggs, milk, liver, yeast or Marmite. In heart failure venesection and vaso-dilators are of definite value, and the bowels should be kept open with salines. During the acute stage contractures must be avoided, and later massage and electro-therapy may prove useful in restoring the atrophied muscles. At this stage a bitter tonic and strychnine mixture may be employed before meals.

EPIDEMIC DROPSY

A nutritional disease occurring in epidemic form in rice-eaters, characterised by fever, wide-spread œdema, cardiac disturbances and sometimes erythematous eruption involving the extremities. Neuritis has been absent in most epidemics. As "Hunger" or "War Œdema" it occurred extensively in the Central Empires during the War.

Ætiology. The disease commences in the rainy season in Bengal, affecting both sexes and being specially common in the third decade. Large numbers of rice-eaters—especially those eating it par-boiled—are often simultaneously

attacked. Some ascribe the disease to decomposition of faultily stored rice in rainy seasons associated with high humidity. Others hold that as there are no reliable means of differentiating it from wet or cardiac beri-beri it should be regarded as a special form of this disease.

Symptoms. These are very similar to *wet* beri-beri, generalised œdema and cardiac dilatation, with enlarged liver and pulmonary congestion being characteristic features. Peripheral neuritis has not been observed in recent epidemics, though there may be complaints of formication involving the feet. Pyrexia is present, associated often with anæmia and sometimes with leucocytosis, and an erythematous eruption may involve the extremities. Diarrhœa is not uncommon and achlorhydria is also reported. Eye trouble—especially glaucoma—is not infrequently encountered.

Treatment. This is similar to that of *wet* beri-beri, and venesection may be necessary for right-heart failure.

PELLAGRA

(*Mal de la Rosa, Mal de Sole*)

Pellagra is a disease of faulty nutrition generally arising in maize-eaters whose diets are deficient in vitamin B₂ and “good” protein. Clinically, there is a symmetrical erythema and pigmentation of the skin in areas exposed to the sun’s rays, alimentary disturbances including sore tongue and diarrhœa, and nervous and physical symptoms often ending in dementia.

Ætiology. Pellagra (*pelle*, skin, and *agro*, rough; or *pelle* and *agra* as in podagra) was first described in Italy (1700), in Spain (1735), and in France (1818), and more recently it has been reported from Roumania, Hungary, Corfu, Lower Egypt, Turkey, Sudan and other parts of Africa, Turkey, the Southern United States, Brazil, Argentine, the West Indies, Mexico, India, China and Japan. People of any race, sex or age are susceptible, but adult women are most affected. It occurs amongst the poorer classes, especially in maize-eaters, and may also follow excessive drinking of alcohol made from maize. It is known in England (14).

Casal in 1735 recognised the disease as due to faulty nutrition, and Funk (12) pointed out its resemblance to beri-beri and suggested vitamin deficiency. It has been regarded (13) as due to amino-acid deficiency, zein, the protein of maize, being defective in tyrosine and tryptophane. Generally it is now attributed to deficiency in Vitamin B₂ (*q.v.*). The maize toxic theory has recently come into prominence: this ascribes pellagra to a toxic substance derived from the maize diet, which can be corrected by sufficient “good” protein or perhaps by sufficient Vitamin B₂, which is found to accompany “good” protein. Secondary pellagra is a rare complication of certain alimentary diseases like peptic ulcer and gastric carcinoma: here defective absorption of Vitamin B₂, as well as dietetic deficiency, may play a part.

Pathology. The skin shows erythema, pigmentation and, later, true exfoliative dermatitis, while emaciation is marked and the viscera atrophic. The heart is small. Glossitis with ulceration and subsequent atrophy of the tongue is found, and atrophic and ulcerative changes have been described in the small bowel as well as ulceration in the colon. Osteoporosis with bony changes occasionally occurs. The most characteristic lesions are found in the spinal cord and consist of sclerosis or degeneration of the posterior and lateral columns—especially Clarke’s column. The latter are most affected in the cervical and upper dorsal region, and the former in the middle and lower dorsal region. There is round-celled infiltration of the perivascular spaces with pigmentation and degeneration of nerve elements. Diffuse leptomeningitis, thickening and adhesions of the meninges, cerebral atrophy and hydrocs of the ventricles may be present.

Symptoms. A pre-pellagrous condition characterised by asthenia, low blood pressure, anorexia and mental depression may reappear annually for some years

before frank pellagra develops. *Alimentary disturbances* appear in early spring : there may be stomatitis and acute glossitis (beet tongue) with aphthous ulceration, denudation of epithelium and, ultimately, atrophy with loss of lingual papillæ. Achlorhydria is the rule and severe non-fatty diarrhœa associated with colicky pain and tenesmus may occur for many months. Anæmia, if present, is generally "secondary" with a low colour index, but occasional instances of megalocytic anæmia have been described. The blood pressure is low, there is associated lassitude and occasionally attacks of vertigo. *Dermal lesions* appear in the early summer and disappear in the autumn. The characteristic features of the eruption are its symmetry, its sharply defined pigmented border and its distribution over areas exposed to the sun's rays. The face, neck, upper portion of the chest, back of the hands and forearms, the dorsum of the feet and the insteps and legs are common sites for the rash which commences as an erythema, like severe sunburn, is associated with itching and burning and may undergo vesiculation. After about a fortnight the epidermis is shed in gray or brown flakes. Pigmentation and thickening of the dermis follow repeated attacks ; ultimately, atrophy ensues, the skin becoming thinned, dry and wrinkled. *Nervous manifestations* resemble those of subacute combined degeneration and consist of pains in the back, tenderness of the dorsal and lumbar spines, increase in the knee jerks (75 per cent.), weakness and stiffness of the gait and, finally, paraplegia with signs of an upper motor neuron lesion. Later, vesical and rectal control are lost and flaccid paralysis may supervene. Sensory disturbances with paræsthesias, tremors involving the tongue, limbs and head and athetoid movements are not infrequent. Of the *mental* features depression, gloom, stupor, loss of memory, insomnia, restlessness and irritability are first observed, and, later, delusions and hallucinations. With repeated attacks over years, melancholia, mania and dementia result.

The growth of children is retarded, but neurological manifestations are not so common in them.

Diagnosis. Where the clinical picture is fully developed little trouble is encountered as the skin lesions are so characteristic. In their absence, however, tabes and subacute combined degeneration of the cord may need consideration in the differential diagnosis, and in those cases where alimentary symptoms are prominent the condition may be confused with sprue. Erythema multiforme and dermatitis venenata may need differentiation when the skin eruption alone is present.

Prognosis. The disease is characterised by remissions and a chronic afebrile course extending up to twenty years. Fever is of serious prognostic significance. About 40 per cent. develop serious mental trouble and many of these die in asylums in countries like Egypt where the disease is endemic.

Treatment. The disease is prevented by reinforcing deficient diets with foods rich in vitamin B₂. Once manifestations have developed the patient should be put to bed on a nutritious diet, low in carbohydrate, and consisting of milk, lean scraped red meat ($\frac{1}{2}$ lb.), tomato juice, brewer's yeast (1 oz. daily), or Marmite and fruit and vegetables. Acid hydrochlor. dil. after meals, $\frac{1}{2}$ –1 drachm in 4–6 oz. water, is useful. Under this *régime* recovery may ensue in from six to twelve weeks, but if relapse is to be avoided the protein and vitamin B₂ requirements of the diet must be permanently adequate.

SCURVY

(*Scorbutus*)

Scurvy is characterised by a profound change in the blood, resulting in hæmorrhages under the skin and in other parts of the body, a spongy condition of the gums, anæmia, and prostration. It is due to the absence of vitamin C—ascorbic acid—from the diet.

Ætiology. It may occur in either sex and at any age ; it has arisen over and over again in circumstances entailing a restriction of the dietary in respect of vegetables and fresh meat. Thus it has been in past times the scourge of sailors on long voyages, so that it is frequently spoken of as sea scurvy, though such a term does not now distinguish it from any other form ; and it has severely affected armies and other large collections of individuals, such as those in prisons, and sometimes even in hospitals. Cases occasionally happen amongst those who could get vegetables, if for any reason, such as poverty, dyspeptic troubles, or mistaken views, they have habitually abstained from eating them.

Morbid Anatomy. In fatal cases of scurvy the lesions are found which have been mostly manifest during life—*e.g.* the hæmorrhages in the skin and the effusions of blood in the aponeurotic sheaths and under the periosteum, and in infants separation of the epiphyses. Occasionally hæmorrhage has occurred on the surface or in the substance of the brain. Frequently the pleural cavities and pericardium contain blood-stained serum. There may be engorgement of the lung with serum or blood, and sometimes it is even gangrenous. Hæmorrhages may also take place into the cardiac muscle, into the pericardium, or into the mucous membrane of the stomach and intestine ; these latter may cause abrasion or ulceration. The liver and spleen are often large, much congested, soft, and friable ; and an acute nephritis is described as occurring in severe cases.

Symptoms. The disease generally comes on insidiously, taking from four to eight months to develop. The patient loses colour, becomes weak, languid, drowsy, or apathetic, and complains of flying pains in the loins or limbs. After a time—it may be a week or more—petechiæ appear upon the skin of the lower extremities and other parts of the body, and as a rule each hæmorrhage is situated around the base of a hair. The spots are small, red or reddish-brown, and not raised above the surface. Some others appear which more or less resemble bruises produced by violence, and large wheals or *vibices* may also be present. These various hæmorrhages occur all over the body ; and there may be large extravasations of blood in the eyelids, or subconjunctival ecchymoses, though very often the face is spared. Associated with this purpuric condition must be mentioned the occurrence of tense, brawny, indurated swellings in different parts of the body, especially in the popliteal space, the bend of the elbow, under the angle of the jaw, and in front of the tibia ; these are due to effusions of blood, or blood-stained fibrin, or simply pale yellow fibrinous material, under the fascia, or between the muscular bundles, or between the periosteum and the bone.

Another feature which is commonly regarded as constant is the condition of the gums. These become swollen, fleshy, or spongy, detached from the teeth, and projecting beyond them in loose, bluish-red masses, which are painful, and bleed on the slightest touch. The teeth become loosened, the patient is unable to chew, and the breath is foetid. The swelling of the gums may be so great that they project from the lips, and ulceration often results. The rest of the mouth is not affected in the same way. The tongue is large and indented. Sometimes the gums are not spongy, but only pale ; and in all cases the change seems to be determined by the presence of teeth, so that it is absent where there is a gap in the series, and in toothless infants and old people.

When all these changes have developed, the patient has a sallow, bloated look, is markedly breathless on exertion, though no physical signs may be detected in the lungs, is subject to fits of syncope, and is totally unfit for bodily or mental exertion. The temperature, however, is generally not raised ; the pulse is variable ; and the urine is usually free from albumin. Hæmorrhage from the mucous surfaces, especially epistaxis, is not uncommon ; and the feet are often œdematous. The blood has the characters of a secondary anæmia, with slight poikilocytosis, polychromasia, and punctate basophilia, and there may be a slight leucocytosis. The red corpuscles fall to 4,000,000 or 3,000,000,

or lower when hæmorrhages are abundant, and there is a low colour index. The coagulation time differs little from the normal.

In more serious cases there is hæmorrhage from the stomach and intestines, or from the lungs; pneumonia, gangrene of the lung, pericarditis, or pleurisy, which may be hæmorrhagic; or enlargement of the spleen and albuminuria. The skin over blood extravasations may slough from pressure or irritation, and leave fungoid and very offensive ulcers. Dysentery sometimes complicates scurvy, but is generally regarded as having an independent origin. The impairment of vision known as *hemeralopia*, or night blindness, frequently occurs; the patient can see clearly and well in the day-time, but in the dusk, or the darkness of night, becomes quite blind, and cannot see his way about. It originates in a disturbance of nutrition of the retina; the ophthalmoscope shows no change in the eye, and normal sight is restored as the scurvy is cured.

Death takes place from increasing exhaustion, with anæmia and emaciation, generally after many weeks. But it may occur more quickly from sudden syncope, from pneumonia or gangrene of the lung, from hæmorrhagic inflammation of the serous membranes, or from cerebral hæmorrhage. In cases which recover the improvement under suitable treatment is at once manifest, and often very rapid; but it is stated that the deeper effusions may leave thickening and fibrous bands, as a result of which the limbs are partly contracted and the corresponding muscles are atrophied. Sometimes the joints are ankylosed.

Infantile Scurvy. This form of scurvy, known abroad as *Barlow's disease*, is seen in children under two years old, and is frequently associated with rickets, another dietetic disease. Scurvy is liable to occur in infants who are fed on sterilised milk, or on malted and other patent foods, and who do not have enough of, or any, fresh milk. Such children do not lose flesh, but become pallid; and then the limbs, especially the lower limbs, are affected, so that they do not voluntarily move them, and cry whenever they are touched or moved, or even when the hand is brought near them. The child lies often with the thighs abducted and the knees flexed, and so may be thought to be paralysed.

The bones are tender, there may be some œdema of the feet, and there may be swellings as a result of sub-periosteal hæmorrhages; and the crepitus of a separation of the bones at the epiphyseal lines may be felt. If any teeth are through, there may be sponginess of the gums with hæmorrhages, as in adults, and sometimes a fungating mass is seen; other hæmorrhages, such as epistaxis or hæmaturia, may occur. The anæmia is of the chlorotic type, and the blood presents an increased number of the mononuclears, some myelocytes, and nucleated red corpuscles.

Diagnosis. There can be little difficulty in recognising this disease when the circumstances are such as have been known to lead to it, but the diagnosis requires care in isolated cases. It is distinguished from *purpura* by the general illness accompanying it, by the spongy gums, and by the deep-seated effusions in the limbs and elsewhere. On the other hand, amongst the poorer classes of the population one may overlook mild cases, where the symptoms mainly consist of vague pains, with anæmia and ill-health, and the patients are likely to disregard a slight change in the gums or a few spots on the skin. An inquiry into the diet will soon determine the nature of the illness. In infants it may be confounded with infantile paralysis, syphilitic epiphysitis, or periostitis.

Prevention and Treatment. It is essential to give food containing the antiscorbutic vitamin. Fresh lemon juice has long been known as a very efficacious preventive and remedy, and it retains its properties to a considerable degree when it is preserved and even when dried (Bassett-Smith). Fresh lime juice is not so efficacious, and preserved lime juice is quite useless. Lime juice obtained its popular reputation because originally the term was used to describe the juice of lemons from the Mediterranean. In the middle of the last century West Indian lime juice was substituted in the Navy under the same

name, but experience showed its uselessness. For soldiers in the field it is probable that dried pulses allowed to germinate just before being used may be the best means of supply of the vitamin; they are convenient owing to their portability. Cabbage is the best vegetable to use, but it must be cooked for as short a time as possible in water without soda. Scurvy has broken out in a camp where the cabbages were cooked with the meat for some hours in a stew. Fresh meat is also of some value. As regards the diet of infants, it is to be noted that cows' milk is one of the less valuable antiscorbutic foods, and such vitamin as is present is diminished by sterilising or pasteurising the milk. It is probable that the vitamin is completely absent in dried milks. In any case, when sterilised or dried milk is used some of the vitamin should be added to the food. The simplest plan is to give the infant a teaspoonful of orange juice; but swedes, which are plentiful and cheap, may also be employed, or tomato juice, a tablespoonful a day at three months, or potato scraped from just beneath the skin after baking. Raw swede juice is obtained by grating the cut vegetable and squeezing the pulp in muslin. For curative purposes large amounts of lemon juice can be taken without causing digestive disturbance if the free citric acid is removed by treatment with calcium carbonate. The pure vitamin, ascorbic acid, which is soluble in water, may be injected intravenously in doses of 100 to 200 milligrammes; it has been used for other hæmorrhagic states such as purpura and hæmorrhagic nephritis. It must be neutralised before being injected intra-muscularly or subcutaneously by dissolving 100 milligrammes in 1 c.c. of a sterile 2 per cent. solution of NaOH.

RICKETS

(*Rachitis*)

Rickets is a disease involving the nutrition and general health of infants and young children, and showing itself (1) in a perversion of the process of ossification, so that the bones are softer than normal, and become bent and deformed by the pressure which they must undergo in everyday use, and (2) in a liability to respiratory and gastro-intestinal infections and to functional nervous disorders.

Ætiology. It is essentially a disease of children, and affects the sexes about equally. The earliest bony changes are noticeable between the ages of six and twelve months. By eighteen months the clinical features are well marked. The children of the poor are much more severely affected with rickets than those of the richer classes, though the latter not uncommonly have it to a slight degree. Its maximum incidence is in winter and spring; it tends to become cured by the summer sunlight, since this increases the amount of vitamin D in the body as already explained; two factors that have been frequently cited as predisposing to rickets—overcrowding in cities and lack of fresh air—are really of importance only in so far as they entail lack of sunlight. *Late* or *adolescent* rickets, which is uncommon, may begin at any time between six and eighteen years.

Pathology. While the absence of vitamin D is the main cause of clinical rickets, there are several other factors which have been shown experimentally to play a part. In the first place, active growth is necessary. In the absence of this lack of calcium or phosphorus by itself does not produce typical rickets, although there soon develops a deficiency of calcium in the bones, which show *osteoporosis* with layers of *osteoid* tissue; but there is little change in the zone of proliferating cartilage. However, rickets may be produced experimentally in an animal by giving a diet sufficient in calorie value but which is either deficient in calcium (calcium rickets), or deficient in phosphorus (phosphorus rickets). Calcification in bone depends on there being present in the plasma a sufficient quantity of calcium (Ca) and phosphoric (PO_4) ions, which unite to form the sparingly soluble salt $\text{Ca}_3(\text{PO}_4)_2$, which is deposited to form bone. In clinical

rickets the serum calcium may be normal, and the serum phosphorus low (phosphorus rickets) (6). In other cases the calcium and phosphorus are both low (10). In any case the condition of the serum is the direct cause of the rickets; the fault does not lie in the bone, since rachitic bone, when incubated in blood serum from a normal child or in solutions containing calcium and phosphate, shows calcification; but this is not the case when blood serum from a rachitic child is used. Vitamin D probably acts by making the intestinal contents acid, which is their normal state, so that the easily-soluble salt CaHPO_4 is formed and readily absorbed. Too much vitamin D produces calcification, especially of the arteries and renal calculi. Without vitamin D the contents become alkaline (11) and the sparingly soluble alkaline salt $\text{Ca}_3(\text{PO}_4)_2$ is absorbed with difficulty (10). Lack of exercise also predisposes to rickets; if the animal is allowed plenty of exercise, much less vitamin D is required to prevent the onset of rickets. In acute rickets there is a lowering of the plasma bicarbonate, which is not due to ketosis (3). Rickets indistinguishable from the rickets of vitamin D deficiency may also supervene in coeliac disease (coeliac rickets). Owing to the large undigested fatty stools there is lack of growth and at the same time too little vitamin D is absorbed so that there is also a deficient absorption of calcium and phosphorus and the bones are osteoporotic. Both the serum phosphorus and calcium are low. On a low fat dietary the clinical condition improves, growth begins, and rickets results, which may be cured in the same way as ordinary rickets. Diarrhoea is another cause of defective fat absorption; but this does not cause rickets, because growth is stopped.

Morbid Anatomy. A longitudinal section of a long bone of a normal infant shows a clean cut end (epiphyseal line) to the shaft (diaphysis), and a disc of whitish cartilage (epiphyseal cartilage) between this and the bony epiphysis in those instances in which ossification of the epiphysis has occurred. In a rachitic bone quite a different picture is obtained. The width of the epiphyseal disc of cartilage is considerably increased. There is no epiphyseal line, but its place is taken by an irregular frayed end to the diaphysis. This frayed end, which is more vascular than normal, is usually scooped out and expanded laterally, the result of pressure, thus producing the clinical sign of enlargement of the epiphysis. To this altered extremity of the diaphysis the term metaphysis is applied.

Normally, between the hyaline cartilage and the bone already developed several layers can be seen microscopically: (a) proliferating cartilage cells without orderly arrangement; (b) proliferating cartilage cells arranged in columns between columns of hyaline matrix; (c) zone of provisional calcification, which makes the columns rigid and so directs the budding capillaries from the marrow against the cartilage cells, which are either destroyed by erosion or become lost in the medullary spaces; the columns are then partly destroyed and partly act as centres round which osteoblasts arrange themselves to form (d) a narrow layer of *osteoid*, i.e. bone which contains no calcium; (e) ossification, produced by deposit of calcium salts in the osteoid.

In rickets this orderly arrangement is completely lost. The zone of cartilage proliferation is increased vertically and laterally, the columnar arrangement being at first manifest, but the cells in the column are more numerous, and soon this design is lost and the cells appear as masses in a hyaline matrix. The zone of provisional calcification is absent, with the result that the marrow vessels grow in all directions. The osteoid layer is greatly thickened and forms the rachitic metaphysis; in it are islands of cartilage cells, wide spaces containing marrow, and in its deeper parts irregular depositions of calcium forming true bone and producing the characteristic dentate frayed appearance of the end of the metaphysis. Osteoid tissue is also present under the periosteum in larger amounts than normally, producing irregular masses or buttresses and eliminating the sharp angles, borders and prominences of the long bones, and giving rise in the membrane bones of the skull to bossing.

When healing takes place, the first thing to occur is the deposit of calcium in the cartilage where the zone of provisional calcification should have been. This at first is a thin irregular line, but as healing advances it thickens, depositions of calcium occur in the osteoid tissue, and the cartilage in the metaphysis gradually disappears.

The typical microscopical findings in rickets are : (1) the presence of large amounts of osteoid tissue ; and (2) the substitution of disorder for order.

The muscles are flabby and wasted. The blood may show a secondary anæmia.

Symptoms. Early in the complaint two symptoms occur which are very constant. One is that the child is restless at night, kicks off its clothes, and lies with its legs and arms exposed ; the other is that when it goes to sleep it perspires profusely about the head and neck, so that the pillow is saturated. But the rest of the body is often dry, and the temperature is normal. The first evidence of osseous changes is the *enlargement* of the ends of the long bones. This is well marked at the wrists, where the ends of the radius and ulna are thickened, and at the ankles and at the knees. If the disease comes on after the child has begun to stand or walk, these accomplishments are given up, and the child " is taken off its feet," as the mothers are apt to explain. If the disease begins earlier, then the art of walking may not be attained until the eighteenth or twenty-fourth month. In either case the child tries to walk before the bones are completely consolidated, and the weight of the body causes the tibiæ and femora to be bent or " bowed," generally with a convexity outwards and forwards. Sometimes there is a convexity inwards at the lower part of the tibiæ, the feet being thus widely separated, and this is to be attributed to the child getting about the floor in a sprawling position, using the feet like the hind fins of the sea lion. If, while still unable to stand, the child crawls much about the floor, the weight of the body falls upon the arms, and the radius, ulna, and humerus get correspondingly bent.

In the chest, enlargement takes place at the junctions of the ribs with the costal cartilages, where a series of nodules are formed, reaching on either side from the first rib near the sternum downwards and then outwards to the twelfth rib in the flank. This has been called *beading* of the ribs, or the *rickety rosary*. Deformity is produced by the action of the diaphragm, which sucks in the ribs at their diaphyses and produces a wide groove on either side of the sternum which is unduly prominent. The patient may also become pigeon-breasted. The lower ribs, however, are often expanded over the abdominal viscera, forming the upper arch of a protuberant abdomen, which contrasts strikingly with the narrow chest above, and is separated from it by a transverse depression (Harrison's sulcus). The latter is roughly at the level of the dome of the diaphragm, where the chest tends to fall in. These various deformities are accentuated by the commonly associated bronchitis or broncho-pneumonia, which hinders the entry of air into the chest. These complications are particularly dangerous, because owing to the soft state of the ribs the act of coughing especially is rendered imperfect, and the secretions accumulate in the lungs. The pelvis does not usually show any deformity in infancy, but in extreme cases of rickets the pelvic aperture is considerably misshapen, being mostly of an hour-glass type, and it may afterwards in females offer very serious obstruction to parturition.

The head, besides presenting large fontanelles and often lines of depression corresponding to the coronal and sagittal sutures (*hot-cross bun* type of skull), acquires a somewhat square shape, the vertex being flattened, and the frontal and lateral regions being rather prominent. In pronounced cases the cranium looks very large in proportion to the face, and the circumference of the skull is often increased. *Craniotabes* is the name given to soft areas on the skull due to deficient ossification, which occur chiefly along the margins of the sutures. Another symptom is the *delay in the eruption of the teeth*, the first of which may not appear until the eleventh or twelfth month instead of the sixth or seventh ; and the order

of their appearance may present many irregularities. The permanent teeth also suffer; the enamel is defective and soft, and the calcium content is lowered. It has been suggested that dental caries in young children is due to lack of vitamin D in the diet of the child or of the mother during pregnancy (9).

In extreme cases there is a considerable stunting of all the bones, as well as the shortening by curvature; and children of eight or ten may be no taller than those of three years old. The bones are also more fragile than normal, and *green-stick fractures* are apt to occur. There is decided laxity of the ligaments and hypotonicity of the muscles, so that there is extra mobility of the joints (*acrobatic rickets*). The liver and spleen are easily felt because they are pushed down by the contracted chest, and are ill supported by the abdominal muscles, and there is abnormal prominence of the abdomen (*pot-belly*). The appetite may be very good, and many rickety children show a perfect or even excessive development of fat (*fat rickets*), but in severe cases there is anæmia. The nervous system may also be seriously involved; rachitic children are very liable to infantile convulsions, including the special forms known as *laryngismus stridulus* and *tetany*. Associated with laryngismus is often *facial irritability*, or Chvostek's sign, in which a gentle tapping over the superficial branches of the motor nerves of the face causes contraction of the corresponding muscles. In rickety children also, rather more frequently than in others, occurs the disorder known as *head-nodding* or *head-shaking* (*spasmus nutans*), which is often associated with *nystagmus*. These occur in babies of from four months to one year, and may be due to imperfectly lighted rooms in the winter-time, thus being comparable to *miners' nystagmus*.

Rickety children may also suffer from symptoms suggestive of scurvy, such as tenderness of the bones. This is not to be wondered at, since the diet may be deficient in vitamins generally.

Diagnosis. This rarely presents difficulties. Sometimes the inability to walk may lead to a suspicion of infantile paralysis (anterior poliomyelitis), but the limbs can at least be moved, and the deformities of the bones should give the right clue. Syphilitic epiphysitis and scurvy cause great pain and tenderness in the bones affected. A very early indication of rickets is given by the plasma phosphatase, which is raised.

X-rays provide a valuable means of diagnosing the extent of the disease and the progress of cure (2). In severe rickets (Plate 46) decalcification of the finer trabeculæ produces a coarsening of the structure of the cancellous bone, and later as the process becomes further advanced the bones can hardly be differentiated from the soft tissues. The appearances vary (1) with the bone examined; thus the end of the humerus in Plate 46 does not show the frayed-out appearance present at the lower end of the radius and ulna; (2) according as the child can still remain fairly active in spite of the disease. In this case, if the lower end of the radius is examined, it is seen that the sharp epiphyseal line becomes lost; the lower end of the diaphysis is expanded laterally; decalcification occurs more rapidly at the centre, so that the end of the shaft becomes cup-shaped. When the child is inactive, the frayed-out appearance is less; there is no scooping out or lateral expansion; but the distance between diaphysis and epiphysis is greater. At the beginning of healing (Plate 47) a new line of calcification appears at the zone of provisional calcification, representing the epiphyseal line of normal bone. Its distance from the diaphysis depends on the width of osteoid tissue and varies directly with the duration of the disease. Gradually the intervening space gets filled up by bone in the form of striæ, and for a long time after healing has occurred a marked contrast may be seen between the dense over-calcified metaphysis and the rarefied cancellous tissue of the shaft in its neighbourhood (Plate 48, cf. Plate 49, normal).

Prognosis. Recovery is the rule, the bones ultimately becoming quite firm and solid; but the deformities, if considerable, will be perpetuated. The

risk to life is from the complications, especially bronchitis, with collapse of lung, convulsions, and laryngismus stridulus.

Prevention. Proper infant-feeding is the all-important point. Breast-feeding is the natural method, and provided there is an adequate supply of milk, and the mother takes a varied diet containing all the accessory food factors, there is no fear that the child will develop rickets or other deficiency diseases. If cows' milk is used cod-liver oil should be given as well to supply the vitamin D. In such a diet the supply of calcium and phosphorus will be adequate. A child properly fed will spontaneously take enough exercise by movements of its limbs and body. It should live in well-ventilated rooms, and should be taken out in the fresh air regularly and get all the sunlight possible.

Treatment. Irradiated ergosterol may be given in the form of "radiostol," 15 minims a day; this is also useful for treating dental caries. Deficiency of vitamin D is usually associated with deficiency of vitamin A; the preparations "radiostoleum" and "radiomalt" contain both vitamins A and D. Cod-liver oil, plain or emulsified, is another valuable drug. It may be given three times a day after meals. The dose of the plain oil is 15 drops for an infant six months old, 20 drops up to twelve months, $\frac{1}{2}$ drachm up to eighteen months or two years, and 1 drachm for older children. Exposure to sunlight is another method of treatment obviously less satisfactory (except in refractory cases) because the dosage is less certain. If there is no sunlight, exposure to an artificial source of ultra-violet light, such as the mercury vapour quartz lamp, the tungsten arc lamp, etc., should be carried out. Plenty of fresh air should be allowed. The deformities of the limbs which remain after rickets is cured may, if extreme, be treated surgically.

Renal Rickets (Renal Dwarfism).—Associated with severe impairment of renal function in young people, there is a high phosphorus content in the blood. The figure for the calcium varies, but is always low relative to the phosphate. Calcium is mobilised from the bones, which tends to make good this deficiency in the blood. During periods of growth the epiphyseal ends of the bones suffer most.

There are three types according to radiological appearances (6): (1) *Atrophic*, in which the whole bone, including the cortex, shows deficient calcification: fractures may be present; (2) *florid* with a characteristic rachitic epiphysis; (3) *woolly, stippled, or honeycomb*, in which the metaphysis is deeper than in ordinary rickets and the proliferating cartilage is more irregular and broken up: the appearance of the skull is often suggestive of Paget's disease.

There is stunted growth; secondary sex characters are late in development; thirst and polyuria are prominent symptoms; the complexion is sallow and the wrinkled face makes the child look older than its years. The urine is pale, of a low specific gravity and usually contains a trace of albumin. The changes in the bones may show themselves in the form of severe rickets or bowing of the legs, but more commonly as genu valgum. The usual age of onset is from five to seven, but cases have been described as occurring at birth or as late as seventeen years. Healing may occur in the bones but the disease is always fatal from uræmia or intercurrent disease. It has been suggested that the disease of the kidneys is secondary to urinary retention associated with dilatation of the urinary tract, but cases are on record associated with congenital cystic kidneys and bilateral renal calculi, and the dilated urinary tract may well be secondary to the increased flow of urine, as in diabetes insipidus.

Ordinary antirachitic treatment tends to make the condition worse by increasing absorption of phosphates and is contra-indicated.

OSTEOMALACIA (*Mollities Ossium*)

This is a disease of adults, almost exclusively women, and is due to lack of vitamin D; it is thus closely allied to rickets.

Ætiology. Among the girls and women of India, who, after running freely about the villages, are shut up in purdah after marriage, a series of cases has been described which illustrates the transition between late rickets, occurring usually between twelve and seventeen, and osteomalacia, which occasionally begins as early as sixteen but may develop after the menopause. Tetany occurs in both, and late rickets and osteomalacia may be present in the same patient simultaneously (7). Osteomalacia was also observed in Vienna in 1918 (8). The patients had subsisted on a diet of bread and vegetables with small amounts of flour and sugar, and a little lard occasionally, and it is noteworthy that rickets and late rickets among young adults were also unusually common in Vienna at this time. Osteomalacia commonly occurs in pregnancy, when any deficiency of vitamin D would naturally produce its most marked effect, and this in time past has led to removal of the ovaries being advocated as treatment.

Morbid Anatomy. The bones may be so soft that they can be cut with a knife or indented with the finger. Nearly the whole of the bone is converted into a soft greasy mass or pulpy material, except perhaps a thin shell of compact tissue just under the periosteum; or even there may be nothing left but the thickened periosteum itself. Microscopically the change seems to be, first, a confusion of the natural minute structure of the bone; the Haversian systems become fused together, and then absorption of the salts takes place from the innermost rings round a canal, so that the substance is gelatinous and transparent. As the same change proceeds in the rings placed farther out, the innermost rings are entirely absorbed, the lacunæ also alter their shape and size, and finally the Haversian systems are destroyed. The bone becomes spongy and porous (*osteoporosis*), and the enlarged medullary spaces are filled with a marrow which is fatty or lymphoid, with giant cells and osteoblasts. In this there are recent hæmorrhages and pigment resulting from former effusions of blood. In some places the medulla may be gelatinous or watery. Chemical analysis of the bones shows that the inorganic constituents are reduced from 68 to 30 per cent.

Symptoms. The first is pain, which is felt chiefly in the lumbo-sacral region and the hips and spreads down the legs, in the spine, and ribs, and not so often in the upper extremities. The bones are tender on pressure, and there is great pain on movement. Consequently there is a characteristic stiff and waddling gait, and the patient uses her arms as much as possible to help her with her movements. She is languid and is disinclined to do anything and there is great muscular weakness. Owing to difficulty in walking she may become bedridden. The joints are not painful. In course of time a change of figure may be noticed; the patient loses height from rounding of the spine or bending of the limbs: then, some day or other, a bone breaks with very little apparent cause, or on slight exertion. As a rule, the fracture heals but imperfectly, and subsequently other bones break. Moreover, the long bones show a remarkable degree of flexibility, so that they can be bent into very strange positions, and the more superficial bones may be indented with the finger. The thorax becomes deformed from the softness of the ribs, and dyspnœa may occur in consequence. In rare cases the bones of the skull may be softened. Tetany may occur.

The disease runs a chronic course, and generally lasts from five to ten years. Death takes place often from exhaustion due to difficulty in breathing on account of the softness of the ribs, or from broncho-pneumonia favoured by the deformity, sometimes during parturition from the obstruction which the distorted (rostrate) pelvis offers to the passage of the fœtus.

The **Diagnosis** is not difficult when the changes in the bones have become manifest. Earlier symptoms may be mistaken for *rheumatism*. Spontaneous fracture also may take place in *sarcoma*, *carcinoma*, *fibrocystic disease*, and *multiple myeloma* of the bones.

Treatment. Vitamin D must be supplied as described under rickets.

SOME CHRONIC INTOXICATIONS

ALCOHOLISM

Acute Alcoholism. The symptoms of drunkenness or intoxication due to taking too much alcohol are familiar, and usually subside as the alcohol passes through the system. Occasionally, however, from the taking of large quantities of spirit in those unaccustomed to it, a fatal result may ensue. It is preceded by unconsciousness, with pupils sluggish or fixed, and generally dilated; small pulse, cold clammy skin, stertorous respiration; and sometimes delirium or convulsions. Very low internal temperatures have been recorded, as if the patient had been lying exposed out of doors.

Sometimes there are unusual reactions, such as wild excitement with violence (*mania a potu*) following the ingestion of comparatively small amounts of alcohol, in specially susceptible persons.

Dipsomania is a periodic over-indulgence in alcohol by persons who in the intervals are temperate or even completely abstinent. Sometimes the recurrent attacks of over-indulgence are the symptomatic expression of phases of a manic-depressive psychosis; at other times they are symptomatic of an epileptic episode; but much more frequently they represent the response of an unstable psychopathic patient who succumbs every now and then to difficulties at home or at business or in other aspects of his personal affairs. In the intervals the patient usually realises that he has drunk too heavily, but may refuse to admit it, or only does so in a modified way. Consequently treatment is difficult.

Chronic Alcoholism. The effects are described in the rest of this section.

Morbid Anatomy. In *chronic alcoholism* the membranes of the brain are commonly opaque and thickened, and the convolutions are shrunken and atrophied from loss of nerve cells and fibres. The changes found in peripheral neuritis, hepatic cirrhosis, etc., are described elsewhere. In death from *delirium tremens* and *acute alcoholism* there is cerebral congestion with small cortical hæmorrhages. Chronic alcoholism may produce changes in various organs, *i.e.* peripheral neuritis, Korsakow's syndrome (see p. 653), polioencephalitis, chronic gastritis, cirrhosis of the liver, myocardial disease, arteriosclerosis, and primary contracted kidney. These diseases are described elsewhere.

DELIRIUM TREMENS

This commonly occurs in those who habitually drink freely, especially after a severe bout. The symptoms may also be brought on in persons who from long-continued excess have acquired unusual tolerance, by sudden deprivation of alcohol, by an injury, such as the fracture of a bone, or by the onset of pneumonia, or other acute disease, or by some mental shock.

Symptoms. The first symptoms are disturbed sleep, restlessness, irritability, and loss of appetite; and with the disturbed sleep there are unpleasant dreams and some delirium. In the morning the patient may be clearly oriented, but the delirium returns at night; the next day the delirium continues, and shows its characteristic features. The patient is constantly talking, addressing either those about him or in response to hallucinations. He talks on his business ("occupation delirium"), frequently changes from one subject to another. His

attention may be secured for a moment, but soon relapses. He may try to get out of bed, or pull the bedclothes about. With this there is very marked tremor of the hands, especially on movement, and the lips and tongue tremble when he speaks. As the condition gets worse he has very definite hallucinations and illusions. Objects in the room or figures on the wall-paper are conceived to be animals or insects; he is constantly seeing cats, dogs, rats, mice, or black-beetles running after him or crawling about the bed; he looks under the bed, or behind the curtains, or peers behind any bystander, and is suspicious of injury from those about him. He may, under some such false impression, strike those who are near; but, as a rule, there is no attempt at violence.

Other symptoms accompany the mental and muscular disturbance. The face is flushed, the conjunctivæ are suffused, the tongue is thickly furred and becomes dry, as the disease progresses. The pulse is quick, soft, at first full, afterwards small and feeble; the temperature rises to 102° or 103° , and there is occasional hyperpyrexia (106° or more). The skin is generally moist or even profusely perspiring; there is albuminuria, and there may be indications of early optic neuritis.

About the end of the third day, with considerable constancy in favourable cases, some improvement begins to show itself. Hitherto sleep has been entirely absent, but now the patient falls into a slumber which may last eight or ten hours, and he wakes much refreshed, the delirium and trembling are less, and gradually improvement takes place in all respects. In more serious cases the pulse is quick and feeble, the patient prostrate; he lies on his back muttering and semi-comatose. Death occurs from exhaustion; from cardiac failure, and this is sometimes sudden; or from pneumonia.

Diagnosis. Delirium tremens may be simulated by *general paralysis of the insane*. Certain physical signs of the latter disease, *e.g.* Argyll-Robertson pupils, may sometimes occur in chronic alcoholism (*see* Polioencephalitis); but the complete syndrome of G.P.I. must be very rare, and in any case examination of the cerebro-spinal fluid should decide the diagnosis.

Treatment. The patient should be kept as quiet as possible in a darkened room undisturbed by visitors. If alcohol has been recently taken in quantity it should be removed by stomach tube. Since the action of alcohol is to prevent the oxygen from the blood stream diffusing into the tissues so that the oxygen pressure in the tissues is lowered, oxygen inhalation, whether by mask or tent, is indicated, and the delirium can be stopped by this means. It is important to ensure sleep, as already described (*see* p. 23). Sometimes the allowance of a small amount of alcohol will procure sleep when hypnotics alone are useless; there should be efficient action of the bowels.

Alcoholic hallucinosis is either a sequel to delirium tremens, or appears independently in a chronic alcoholic. The patient remains completely oriented and the intellectual and sensorial functions are for all practical purposes intact; but there is a mainly auditory hallucinosis, usually of a persecutory kind, and often with a homosexual colouring. Hallucinations of the other senses also occur, especially odours and tactile paræsthesiæ, which are interpreted in harmony with the content of the auditory hallucinosis. Often the auditory hallucinations have the rhythm of some real sound in the environment, and often also they are of persons speaking about the patient, instead of directly to him. There is a certain amount of apprehension, in relation to the persecutory nature of the hallucinatory ideas, and suicide is sometimes attempted as a means of escape.

The onset of the condition is acute as a rule, and after weeks or months, complete recovery usually occurs. How far the condition is actually the result of alcoholism is doubtful; in many cases, the patient's personality has much to answer for; probably the alcoholism and hallucinosis are like the symptomatic outcome of the latter.

On account of the antisocial nature of the hallucinatory content and its effect

on the patient's behaviour, and of the possible suicidal attempts in the earlier stages, as well as of the necessity for avoiding the provocative alcohol, close nursing supervision is imperative, usually in a mental hospital.

CHRONIC ALCOHOLISM

Symptoms. Muscular tremor is one of the first indications of the effects of the poison upon the nervous system. The hands are unsteady, and the tongue trembles when it is protruded. The patient is restless and irritable, he sleeps badly, and wakes unrefreshed, with a feeling of prostration that tempts him to take stimulants at once. Sinking feelings are frequently complained of, which require, according to the patient, to be met by fresh doses of the favourite drink. As things get worse the patient is unequal to any sustained mental effort; even the simplest business transaction must be preceded by a glass. Sensory disturbances may be also present, such as buzzing or rushing in the head, vertigo, *muscæ volitantes*, flashes of light, or diffused headache. There may be severe neuralgic pains in the legs, possibly the early signs of neuritis. In later stages the mind is seriously involved. Judgment, intellectual capacity, volition, and the moral sense are all weakened. Lack of consideration for his family, actual cruelty, sexual misdemeanour, irritability leading to violent outbursts, inefficiency and lack of interest in business affairs, and failure or refusal to recognise his condition, are characteristic of the chronic alcoholic. Ideas of jealousy and actual delusions of unfaithfulness are not uncommon.

With the occurrence of the first symptoms the functions of the stomach are often disturbed. The patient vomits in the morning directly he rises from bed, he is quite unable to eat any breakfast, and his appetite generally is deficient. The tongue is furred and the breath foetid. The eyes are suffused, and the face may be tinged with yellow. In course of time the minute venules of the cheeks become dilated, the nose is red and thickened, and sometimes rosacea develops. The face becomes more and more bloated, and the blotching with dilated venules is more marked.

In addition to diseases directly resulting from alcohol detailed above, these patients are liable to succumb with great rapidity to any acute illness such as pneumonia or erysipelas.

Treatment. Usually the patient wants temperance, not complete abstinence, to be recommended; yet the latter is the only rule which will give him a chance of keeping free of his alcoholism. Residence in a hospital or nursing-home over many months, where the doctor can be certain that no alcohol is obtained, enables a habit of abstinence to be begun. At the same time the physician should approach the problem psychotherapeutically; in this way the patient can sometimes be taught to face his difficulties without resort to alcohol. Short of this, the limitation of opportunity, social or otherwise, for drinking is important, *e.g.* patients of this type have been known to remain abstinent after a course of psychotherapeutic treatment in a special hospital, together with a change of occupation on their return to work. The treatment of alcoholism is impossible when the patient refuses all co-operation, because, except in the very advanced stages, he is capable of assuming a normal demeanour at an interview, so that certification as insane is impossible.

Alcoholic pseudoparanoia is commonly a schizophrenic psychosis, with a history of alcoholism. Korsakow's syndrome is described elsewhere.

CARBON MONOXIDE POISONING

Coal gas is nowadays the favourite means of suicide. The immediate effects of the inhalation of coal gas are headaches, nausea and vomiting, followed by increasing dimness of vision, and then by an acute organic mental reaction—

delirium or coma ; there may be widespread painful erythematous patches. If death does not occur, recovery is commonly complete, but in a few cases a chronic organic reaction—considerable memory-loss, defect of attention, lack of insight and deterioration in behaviour—follows, commonly after a period of some days or weeks of apparent recovery. Focal neurological signs and peripheral neuritis may also follow. In chronic poisoning, as may occur in men who are exposed for long periods to low concentrations of the gas, *e.g.* workers in garages, there is compensatory increase in the hæmoglobin and red cells of the blood.

Pathology. In the acute stages CO-hæmoglobin is produced with its characteristic spectrum. There are hæmorrhages in the brain ; there is congestion, with or without hæmorrhage, in the heart, muscle, liver and other organs, and degeneration and atrophy of the cells—changes produced by the oxygen want.

The **Treatment** in the acute stage consists in administering oxygen containing a mixture of 5 per cent. CO₂ or oxygen alone ; there is no doubt that addition of carbon dioxide is really important. When available an oxygen tent should be used. Artificial respiration must be used if necessary ; if possible, with the apparatus described elsewhere (*see* p. 44).

LEAD POISONING

(*Plumbism*)

This occurs among those who have to do with lead or salts of lead, either in the preparation of those substances or in industries in which they have to be used. The latter are specially printing, plumbing, type-founding, type-setting, glazing of china and pottery, house-painting, and manufacture of electric accumulators. It also arises accidentally as the result of impregnation of drinking water with lead from service pipes or cisterns. This occurs when the water is soft, but not when it is hard. Lead may cause poisoning when taken as an abortifacient. It enters the system by the respiratory mucous membranes, by the alimentary canal, or very uncommonly through the skin. Legge and Goadby showed that the first is by far the most common way, lead salts being inhaled as a fine dust, *e.g.* by painters, while they are undertaking the preliminary process of rubbing off the old white lead paint. Susceptibility to lead-poisoning varies greatly. Women are more susceptible than men. The tendency to be attacked is increased by starvation, ill-health, exposure to cold, and indulgence in alcohol, and by the pre-existence of gout, syphilis, or disease of the kidney.

Pathology. After absorption of lead through the lungs, it circulates in the blood in the form of colloidal lead phosphate ; it then becomes stored as phosphate in the bones and to a much smaller extent in other tissues ; if it is absorbed through the alimentary tract a rather large proportion is found in the liver, as the lead is transported there through the portal circulation. Lead is chiefly excreted through the alimentary tract, and the bile is an important vehicle, since the liver secretes lead into the bile ; lead is also excreted by the kidneys into the urine.

Symptoms. *Acute poisoning* may follow the sudden ingestion of a large dose of lead. The symptoms are abdominal pain, vomiting, diarrhoea, weakness and collapse, and there may be acute anæmia from blood destruction. In *chronic poisoning* there are four early symptoms—pallor of skin, lead line, punctate basophilia and secondary anæmia.

The *blue line* on the gums, or *lead line*, has mainly a diagnostic importance, showing that lead has been taken into the system. It is a dark slate-coloured or black finely dotted line, which forms close to the teeth either actually at the edge of the gum or just inside the free margin ; but it may occur in that part of the cheek opposed to the teeth. It consists of a deposit of sulphide of lead in the tissues around the vessels ; this results from the union of lead with sulphur pro-

vided by albuminous substance (partly contained in "tartar") at the edge of the gum. Where teeth are absent there is no blue line, and also if the teeth are kept exceptionally clean; or it may be seen only in portions of gum rising between the teeth. The blue line may exist without any other symptoms of plumbism; it persists for from eight days to three months, or even much longer, after all entry of lead into the system has ceased. The lead line must be distinguished from a blue discoloration which accompanies a marked degree of pyorrhœa alveolaris.

Punctate basophilia is one of the earliest signs of lead poisoning; the granules are formed from the basophilic substance of the younger corpuscles by the action of lead. Lead phosphate is also deposited in the covering membrane of all the red cells, making them shrink and diminishing their permeability, and so also their fragility to hypotonic salt solutions. In spite of this the membrane is so brittle that the cells break down more readily from slight trauma in the circulation producing a secondary anæmia, and in severe anæmia there is anisocytosis, poikilocytosis and polychromasia. There may be a moderate leucocytosis, in which the lymphocytes, large mononuclears and eosinophils are increased in numbers.

At any stage in the disease acute developments or "toxic episodes" may occur, such as colic, paralysis, encephalopathy, and optic lesions, while other changes associated with chronic lead poisoning become gradually established and these are also described below.

Lead Colic. This is a form of intestinal colic. After a period of impaired health, often associated with nausea and vomiting and always with obstinate constipation, the patient is seized with severe spasmodic pain in the lower part of the abdomen or at the umbilicus; he is cold, pale and often drenched with sweat; during the attack the abdominal muscles are contracted, and the pain is rather relieved by firm pressure in many cases, but often the abdomen is tender, and it is generally retracted. On examination the intestines may be felt to be contracted, forming irregular masses in different parts of the abdomen. Sometimes there is vomiting, and the bowels are nearly always confined. The pain diminishes for a time and then recurs, and it is generally relieved in the course of one to three or four days. It is due to spasmodic contraction of the intestine from the direct action of the lead on the muscle fibres.

Lead Paralysis. This is often described under the head of multiple neuritis, but it has also been thought to be due to a selective incidence of the poison upon the motor cells of the spinal cord.

However, lead probably acts primarily on the muscles, and the nervous lesions may be secondary. It picks out especially those muscles which are liable to fatigue; the lactic acid produced in these circumstances dissolves the circulating lead phosphate which becomes deposited in the muscle cell.

The characteristic feature is the distribution of the paralysis, which is in most cases confined to the upper extremities, and though it may affect one arm before the other, is usually symmetrical. The first muscles to suffer are the long extensors of wrists and fingers, so that when the arms are held out with forearms pronated, the hands and fingers hang down. Hence the affection is sometimes known among workmen as "the dangles." The index and little fingers, possessing additional extensors of their own, suffer less than the ring and middle fingers, which may be affected alone. If the hand and the first phalanges are supported in the horizontal position, the remaining phalanges can be extended, showing that the lumbricales and interossei are still active. The supinator longus as a rule escapes. As the result of long-continued weakness backward displacement of the carpus sometimes occurs, and a prominence forms on the back of the wrist.

While this is the most characteristic form of lead palsy other groups of muscles are sometimes affected. Of these the commonest are—(1) the intrinsic muscles of the hands; (2) the muscles of the shoulder girdles, especially biceps, brachialis anticus, deltoid and spinati; and (3) the anterior tibial group in the lower limbs.

Although there may be complaint of muscular pains at the onset, there is no peripheral sense of numbness or tingling, nor any cutaneous anæsthesia. The affected muscles waste, and on electrical examination show the reaction of degeneration.

Encephalopathy. This may be in the form of hemiplegia, or of hemianæsthesia. More severe cases, not infrequently fatal, occur in which convulsions, delirium, and coma, with, perhaps, optic neuritis and some fever, are the symptoms. Such cases often run a very acute course, and appear to be more frequent in females (Oliver). Anæmia is the first symptom, and then colic, headache, vomiting, diplopia, or defective vision from optic neuritis. In a few days the patient is convulsed, becomes comatose and dies. In other instances, there is mental disturbance in the form of insomnia, visual hallucination and violent excitement.

Ocular Lesions. These are frequent, and include inequality of pupils, diplopia from paralysis of certain eye muscles, optic neuritis with or without hæmorrhages, neuro-retinitis, primary and secondary optic atrophy, and a bilateral amblyopia without change in the fundus, similar to uræmic amaurosis. The latter lesions are often due to a lead nephritis.

Albuminuria is a result of lead poisoning in two or three ways. It may occur temporarily in lead colic; and it is often present with œdema and diminished output of urine owing to tubal nephritis, as in cases of encephalopathy (Oliver), or of granular kidney in more chronic conditions of plumbism. The relations of lead, gout, and granular kidney are very close. Gout, at least in the south of England, is common in those who suffer from chronic lead-poisoning, which causes, it is said, diminished excretion of uric acid. And it has also been observed that sufferers from gout are very readily affected by lead.

The *liver* changes are fatty infiltration, congestion and deposit of hæmosiderin. Van den Bergh's test is commonly positive and sometimes there is frank jaundice (1).

Lead poisoning affects the functions both of menstruation and of gestation. Menorrhagia is very common, but occasionally there is amenorrhœa or dysmenorrhœa. In pregnant women there is a large proportion of miscarriages and stillbirths; and of children born alive many are under weight, and many die within a year. Amongst those who survive, convulsions, imbecility, and idiocy are above the average proportion.

Diagnosis. This depends for the most part upon the history of lead poisoning, upon the presence of a lead line upon the gums, and upon the discovery of lead in the excretions. The history may have to be investigated with the greatest care, as lead may get into the system by the most unexpected means. If paralytic symptoms are present, a history of colic is often obtainable, and in nearly all cases the lead line is present, though in very cleanly persons it may only be found between the teeth, or possibly not at all. The common type of lead palsy is readily distinguished from musculo-spiral paralysis by the escape of the supinator longus in the former and the simultaneous affection of both arms.

Lead is present in the fæces in larger amounts than in the urine, so that the former should be used when lead is being tested for; but the presence of lead in the fæces does not prove that it is in the system; only its presence in the urine proves this.

Prognosis. Recovery, though slow, is, with proper treatment, usually complete. If at the end of two years from the commencement of treatment any weakness still remains, it is likely to be permanent. Severe cerebral symptoms endanger life, but if death does not occur, recovery may be complete.

Prevention. It is essential to remember that dust and fumes are more important causes of industrial plumbism than ingestion from dirty fingers. The measures employed to minimise dust and fumes are: Exhaust ventilation applied by large hoods over the work benches or locally to the point where fumes

are being produced (*e.g.* in "lead burning")—insistence on wet processes, including the daily hosing of sheds in accumulator works, etc.; the complete enclosure of necessarily dusty processes in dust-tight chambers. In the painter's trade the mixing of paints from dry powders and the rubbing down of painted surfaces (except with oiled sand-paper used *wet*) are now illegal. Domestic lead poisoning must be prevented by forbidding the use of lead water-pipes in certain areas, and by avoiding the use of lead and pewter vessels for cider and wine.

Treatment. The patient should give up his occupation, or prevent in whatever way may be necessary the introduction of more lead into the system. The most effective way of eliminating lead from the system, *i.e.* from its place of storage in the bones, is to give a low calcium diet, which may include meat, liver, potatoes, rice, tomatoes, bananas, peeled apples, tea, coffee, sugar and salt-free "nephritic bread," and butter fat prepared by melting butter in hot water and skimming off the fat. Milk, eggs, green vegetables, and many fruits are excluded. An acidosis is then produced which dissolves out lead phosphate (and calcium phosphate) from the bones so that it is excreted. 200 c.c. of dilute phosphoric acid or 10 grammes of ammonium chloride daily, in 10-hourly doses, are taken dissolved in plenty of water. A less effective method, but one that may be necessary when there is nephritis, is to give 20 to 40 grammes of sodium bicarbonate daily without dieting. Potassium iodide (5 to 15 grains) is also not very effective. Such treatment must only be given when there are no acute developments, and must be carefully watched, since, by the mobilisation of the lead, it may give rise to them. When acute symptoms are present a high calcium diet is advisable, *i.e.* 3 pints of milk, and calcium lactate 30 grains daily (3), to drive the lead into the bones.

Colic generally yields readily to a full dose of opium or an injection of morphia, combined with a simple purgative, *i.e.* an ounce of castor oil with 15 or 20 minims of tincture of opium or magnesium sulphate. Hot fomentations and pressure to the abdomen and enemas may be tried. Atropine, nitro-glycerine and benzyl benzoate may be used freely. In *paralytic affections* appropriate splinting is of the first importance, the paralysed muscles being placed in the position of relaxation. Massage, movements, and galvanism are also valuable. This treatment should be carried out for months. For *acute cerebral attacks* Oliver recommends the inhalation of nitrite of amyl and lumbar puncture with removal of from 1 to 3 ounces of fluid. Oxygen might be tried as in alcoholism. *Anæmia* must be met by suitable treatment with iron preparations (*see* p. 431). Liver extract might be tried.

CHRONIC MERCURIAL POISONING

The use of acid nitrate of mercury in the felting of hair in felt hat manufacture is the greatest cause of chronic mercurial poisoning in the world to-day. Many workers are affected with the anæmia, salivation, and stomatitis which are the familiar results of overdosing with mercury used as a drug.

The characteristics of mercurial poisoning are excitability of temper (mercurial "erethism") and the tremulous movements of the limbs and body known as "mercurial tremors," or "trembles." They affect the arms first, and then spread to the legs and the muscles of the rest of the body. The movements are at first brought out only by excitement, later whenever the patient makes any muscular effort, and finally they become constant, and even persist to a certain extent during sleep. The tongue is tremulous, and speech is hurried, abrupt and jerky. Ataxia and even paralysis may be present in bad cases, and the patient may be quite unable to walk without support. In some cases there are tonic spasms of the flexors of the forearms after violent movements, or hard work. Anæsthesia, vertigo, delirium, hallucinations and restless excitement may also occur. In the earlier stages there is some resemblance to disseminated sclerosis, but there is no nystagmus; and if the movements become constant, paralysis agitans is, to a certain extent, simulated. Mercury also causes tubal nephritis.

Recovery may take place if the disease is not too advanced.

Treatment. Removal from the fumes of mercury is essential. Tonics and iodide and bromide of potassium are of most value as drugs ; and sedatives, such as opium, chloral and belladonna, may be useful.

CHRONIC ARSENICAL POISONING

This is less common than lead poisoning, but it may arise in the following circumstances : among persons employed in arsenic factories, and in industries involving the use of arsenical pigments ; among persons using such coloured articles as, for instance, certain grey and green wall-papers ; occasionally from the use of large doses of arsenic in medical treatment ; and in accidental impregnation of beverages with arsenic, such as occurred in the Manchester epidemic of peripheral neuritis, when an impure sulphuric acid was used in the process of malting. Poisoning by arseno-benzol has already been described.

Symptoms. In the case of exposure to arsenical dust, which is highly irritating, the effects are manifest on the skin and accessible mucous membranes ; when the arsenic is taken internally, the alimentary mucous membrane, the peripheral nerves, and the skin through the circulation are affected. In the first case the prominent feature is irritation of the skin resulting in a form of eczema or dermatitis, which is seen especially in the warmer or moister parts, such as the axillæ, between the scrotum and thighs, at the edges of the nostrils, and the eyes. Redness of the conjunctiva and smarting of the eyes, sore throat and irritation, with frequent hawking, are also present. Later there are symptoms of general poisoning, but these are more prominent when the poison has been injected in small doses frequently. There is gastro-intestinal irritation, with perhaps sickness, diarrhoea, and abdominal pains. With this are often combined emaciation, weakness, muscular cramps, and frontal headaches. Peripheral neuritis is a characteristic feature (*see p. 651*), and a disorder of the skin of which pigmentation and thickening of the epidermis, especially on the palms and soles, or *keratosis*, are the prominent features. Transverse ridges and furrows appear on the finger-nails ; and in acute cases curved white lines (*leuconychia*) have appeared, showing interrupted nutrition at the time of the poisoning.

Treatment. This consists in removing the cause, when the symptoms will subside ; medicinally iodide of potassium may be given in 5-grain doses. Peripheral neuritis may, however, persist for several months.

CHRONIC MANGANESE POISONING

Commercially manganese is used in making chlorine, paint, varnish, enamel, and linoleum, for the marbling of soap and in the manufacture of steel.

The clinical features of manganese poisoning resemble paralysis agitans and suggest that there is a lesion in the corpus striatum. There are emotional disturbances with periods of uncontrollable laughter or weeping, mental languor, muscular rigidity and tremor. The gait is shuffling, and there is a tendency to fall down. There are no signs of disease of the pyramidal tracts (2).

DISEASES OF THE NERVOUS AND MUSCULAR SYSTEMS

UNDER this heading we have to deal with disorders of the brain, spinal cord and nerves—disorders which manifest themselves through the functions of motion, sensation, the special senses and the intellect and emotions.

Although the nervous system is affected by the same pathological processes as the rest of the body, there are certain peculiarities of structure and function which distinguish the effects of disease of this part from all others.

The first point of importance is the extreme specialisation of function which reaches its height in the higher parts of the central nervous system. Thus it happens that a minute lesion may produce symptoms and signs which we can attribute with certainty to the situation of the disease. Such a group of symptoms and signs is said then to have a *localising value*.

A further consequence of specialisation of structure is the tendency of certain poisons—bacteriological or chemical—constantly to pick out certain groups of nerve cells or fibres. This *selective incidence* must depend upon peculiarities of a chemical or physical nature resident in the nerve cell which render it especially liable to some poisons, resistant to others. Thus it happens that a particular sign comes to be very frequently associated with the same pathological process. But we must always remember that the *sign is the result of the localisation of the lesion and not of its pathology*. The spirochaetal poison of syphilis, for instance, has a selective incidence upon minute centres in the mid-brain which control the reaction of the pupils to light. Loss of the pupillary reaction to light—the Argyll Robertson pupil—is therefore one of the commonest signs of nervous syphilis. But we are not entitled to conclude that the Argyll Robertson pupil is *always* due to syphilis. Any other cause operating in the same situation *may* produce the same sign—for instance a tumour, or the virus of encephalitis lethargica.

A second distinctive feature of nervous diseases is due to the relatively enormous length of the nerve cell. When the axon of a nerve cell is injured or diseased the distal part undergoes degeneration down to its peripheral twigs. Thus a lesion of the first thoracic nerve root within the vertebral column will result in degeneration of nerve fibres supplying the small muscles of the hand, and consequent paralysis and atrophy of these muscles. And a lesion of the cells in the upper part of the motor cortex will cause degeneration of the pyramidal fibres coursing down the spinal cord as far as their termination in the lumbar enlargement, with paralysis of the lower limb. The lesion, therefore, may be at a very considerable distance from the part in which the symptoms are manifest.

A third striking feature of the nervous system is the way in which its parts are enclosed, and, as it were, insulated from other tissues—the central nervous system by means of the meninges and the peripheral nerves by their neurolemmal sheaths. Associated with this is the observation that primary tumours of the nervous system never erode the meninges—however malignant they may be within these bounds—or invade other tissues. Nor, on the other hand, do malignant growths elsewhere ever directly invade nervous tissue (although, of course, they may produce damage by mechanical compression).

Another peculiarity of the nerve substance is the absence within the brain and spinal cord of any fibrous supporting tissue, its place being taken by the much more delicate neuroglia. Hence the tendency of suppuration to spread widely instead of becoming limited by a fibrous barrier. There is a similar liability in hæmorrhage, whether accidental or the result of vascular disease. The pressure of the effusion easily suffices to tear through the fine neuroglia fibrils and excavate the substance of brain or cord. In conditions of chronic inflammation, however, the neuroglia cells proliferate and form an excess of fibrils which leads to an increased density. Moreover, the degeneration products of nerve fibres undergoing "secondary degeneration" (e.g., a degeneration of pyramidal fibres in the cord secondary to a lesion of the internal capsule) appear to provoke a similar reaction on the part of the neuroglia cells, so that after the decayed nerve fibres have been absorbed by scavenging cells their former course is marked by an increased density of neuroglia, which is often both visible and palpable. Such appearances led, in the early days of neuro-pathology, to the assumption that the overgrowth of neuroglia was the primary disease process, the destruction of nerve cells being a secondary result, and the pathological process at work was named "*sclerosis*." We now believe that this conception was inaccurate, and that the primary effect of injury or disease is degeneration of the nerve cells with secondary neuroglial overgrowth.

A further point of importance is the fact that the brain and cord are enclosed in a tough fibrous membrane within a bony cavity. There is little room, therefore, for expansion, and a bruise such as elsewhere in the body would result in local swelling and pain, or a benign tumour not invading the nervous tissues, may readily cause serious damage by compression.

Apart from the spread of organisms by direct continuity there are two main channels through which bacteria or toxins may gain entrance to the central nervous system. The main pathway is through the blood stream. But in at least two diseases—tetanus and diphtheria—the toxin travels centrally from the site of infection along the nerve fibres.

Before proceeding to the systematic description of the diseases of the nervous system, something must be said of its general anatomy and physiology, and of the clinical methods of investigating the symptoms which its diseases produce.

APPLIED ANATOMY AND PHYSIOLOGY

Our knowledge of the structure of the central nervous system in man greatly exceeds that of its function. There are many parts, which, though well defined by the anatomist, are clinically "silent." Partly, perhaps, for this reason the lesions afforded by disease do not lend themselves easily to systematic exposition in terms of physiology. In the following pages an attempt will be made to present simply that which is of practical value.

The Lower Motor Neuron. This comprises a cell situated in the anterior horn of the spinal grey matter, or one of the motor nuclei in the brain stem, and an efferent fibre which, passing through one of the anterior spinal nerve roots, or motor cranial nerves, has its termination in a motor end plate in contact with a striped muscle. The function of the lower motor neuron is the conduction of all nervous impulses to the muscle from the central nervous system, whether these are concerned with voluntary movement, postural tone or reflex action. The nutrition of a muscle also depends upon its connection through the motor fibre with an intact motor cell. If this connection is broken or if the cell is damaged, the muscle wastes.

The signs of a lower motor neuron lesion, therefore, are loss of voluntary power, loss of tone, loss of reflex action, and wasting, in the muscles affected. When the lesion affects the motor cells directly and progress of the disease is

forms of sensibility on the opposite side of the body, though, as the fibres of the fillet and those of the spino-thalamic tract lie apart up to the level of the mid-brain, either may be affected separately. A lesion above the optic thalamus will result in an incomplete sensory loss on the opposite side of the body. Some degree of appreciation of contact, pain, and extremes of heat and cold will be preserved. Actually, in the case of lesions above the thalamus sensation is, as a rule, most severely affected in the hand and foot, with relatively little impairment over the proximal parts of the limbs and the trunk. The nearer the lesion is to the cortex, the more likely it is that the sensory defect will be of a dissociated type with little affection of the cruder forms of sensation and severe disturbance of the spatial and discriminative forms of sensibility.

Lesions of any part of the sensory pathway may give rise to sensations described as numbness, tingling, or pins and needles—these being called paræsthesiæ. In the case, especially, of lesions which cause partial loss of cutaneous sensation, there is often an associated hyperæsthesia—that is, although the stimulus required to produce any sensation is greater than normal, the sensation when it comes is of abnormal character, unusually vivid, as a rule painful, and with a tendency to spread more widely than normal. Pain is a variable quantity in lesions of the sensory nerves. When the peripheral twigs are involved it is not, as a rule, a marked feature, but may be severe with lesions of the nerve trunks or their branches, and is of almost constant occurrence in disease of the posterior nerve roots. Lesions of the longitudinal tracts in the spinal cord do not, as a rule, give rise to pain, though there are some striking exceptions (as in *tabes dorsalis*). Lesions at or near the thalamus are apt to cause severe pain of widespread distribution with associated hyperalgesia.

Reflex Function. A reflex action may be defined in its simplest form as an exhibition of activity in an effector end organ—muscle or gland cell—in response to stimulation of a receptor end organ, the stimulus being conducted from receptor to effector through the central nervous system. The act is not voluntarily performed though the individual may be conscious of it. The simplest reflex arc therefore must comprise at least two neurons, receptor and effector. Between these, as a rule, intervene many connecting, or association, fibres.

The most primitive reflex systems are those concerned with the regulation of the alimentary and excretory functions. The centres for these reflexes are ganglion cells lying in the walls of bowel and bladder. Therefore, even when the spinal cord is destroyed reflex activity of this kind continues. Under normal conditions, however, the primitive or lower reflex centres are in some measure controlled by the activity of higher centres. In some instances and to some extent the lower centres are under voluntary control. When, as the result of disease, the control imposed by the higher reflex centres, or by the will, is lost, the activity of the lower centres may be increased and give rise to positive symptoms. The reflex functions which are of most importance in clinical neurology, are those concerned with the regulation of postural tone and equilibrium, with micturition and defæcation, and with the protection of the body from excessive or noxious stimulation.

Regulation of Postural Tone. From animal physiology, we know that in the cat transection of the brain stem between the level of the red nuclei and that of the entry of the fibres of the eighth nerve, results in a generalised increase of muscular tone, which follows a definite pattern (predominance of the extensor groups) and is known as decerebrate rigidity. In man, as we have already observed, following a lesion of any part of the pyramidal tracts, there is increased tone in the affected muscles which also follows a regular pattern. The phenomena are closely comparable, and it is assumed that in both cases the cause is release of reflex tonic centres from control.

As a result of the increased muscular tone, reflex contraction in response to sudden stretching is much enhanced. It is, therefore, easier to make a muscle

contract by tapping its tendon, and the contraction is brisker. Persistent stretching of a muscle by leverage at the joint may result in a brisk contraction whose rebound stimulates further contraction and so on, the phenomenon known as clonus.

Diminution or abolition of the tendon reflexes may be caused by any lesion which interrupts the reflex arc concerned. This reflex arc comprises afferent fibres from the muscle and tendon, association fibres which run for some distance in the posterior columns before entering the grey matter to make contact with the anterior horn cells, and the lower motor neuron units. The tendon jerks, therefore, may be impaired or lost in disease of the peripheral nerves, posterior columns, central grey matter of the spinal cord or anterior horn cells.

The tendon reflexes of chief importance, together with their spinal and peripheral pathways, are as follows :—

Reflex.	Spinal Segment.	Peripheral Nerve.
Biceps jerk. .	C. 5 and 6	Musculo-cutaneous
Triceps jerk .	C. 6 and 7	Musculo-spiral
Supinator jerk .	C. 5 and 6	Musculo-spiral
Knee jerk . .	L. 2, 3 and 4	Anterior crural
Ankle jerk . .	S. 1 and 2	Sciatic

Equilibrium. The maintenance of the correct posture of the body in relation to the force of gravity, of the head in relation to the body, and of the eyeballs in relation to the head, is a function of postural tone. As, however, disorders of balance constitute an important group of neurological symptoms, the physiology of equilibrium deserves a separate note.

The maintenance of equilibrium depends mainly upon afferent impulses received from three sources, the eyes, the labyrinths and the muscles themselves. These afferent impulses are co-ordinated in reflex centres situated in the brain stem and cerebellum to produce a smooth outflow of tonic impulses to the appropriate muscles.

The impulses derived from the muscles themselves are the most important. A man with both labyrinths destroyed can maintain the erect posture and walk blindfold, whereas, on the contrary, a patient with loss of muscular sensibility from destruction of the posterior columns exhibits a gross disturbance of balance despite the integrity of eyes and labyrinths. The impulses derived from the eyes are of least importance.

The main function of the labyrinth in man is to maintain the balance of head and eyes. The labyrinth on each side directs the head and eyes towards the mid-line. Thus, in the case of a destructive lesion of the left labyrinth, the occiput tends to fall towards the left shoulder; and when the patient is asked to look towards his extreme right the eyes swing back towards the left owing to the unopposed action of the right labyrinth; the consequence being, if the patient persists in the attempt at deviation to the right, a regular oscillation of the eyeballs known as nystagmus.

The symptoms resulting from destructive lesions of the labyrinths vary greatly with the acuteness of the lesion. With gradual destruction, the co-ordinating centres are able to deal by means of compensation, so that no symptoms appear, but an acute lesion may produce violent giddiness and even throw the patient to the ground. The exact position of the co-ordinating centres in man is unknown, but lesions in any part of the brain stem from the medulla to the level of the posterior end of the third ventricle, or of the cerebellum, are apt to produce disturbance of balance and nystagmus.

Micturition. The control of the bladder in man has recently been investigated by Denny-Brown and Robertson, whose main conclusions are as follows :—

The nerve supply of the bladder and its sphincters (internal and external) is derived from three sources. Of these the most important is the pair of pelvic nerves arising from the second, third and fourth sacral roots. Stimulation of these nerves causes contraction of the bladder wall (detrusor) with relaxation of the internal sphincter. The pudic nerves, also derived from the second, third and fourth sacral roots, innervate the external sphincter, which contracts when they are stimulated. The third source of supply is by way of the hypogastric nerves derived from the eleventh and twelfth thoracic and first lumbar roots. Stimulation of these nerves causes contraction of the internal sphincter with some degree of inhibition of the detrusor. Section of both hypogastric nerves in an animal, however, causes little or no disturbance of micturition. This source of nerve supply therefore appears to be of relatively little importance. After all these nerves have been severed, and the vesical plexus is thus isolated, the bladder will continue to discharge its contents periodically.

Under normal conditions the accumulation of fluid within the bladder sets up rhythmic contractions of its wall. These contractions are controlled by a restraining effect which at low volumes is subconscious in its operation. This restraining effect can be enhanced or removed by voluntary intent. Thus the will to urinate results in increased force of contraction with reciprocal relaxation of the internal, and subsequently of the external, sphincter, and the act of micturition occurs. On the other hand, even when the bladder is full, the contraction can be inhibited by an effort of will, which together with voluntary contraction of the external sphincter prevents micturition. The paths by which this control is effected lie in close proximity to the pyramidal tracts.

Passive distension of the bladder gives rise to a sensation of increasing discomfort. The rhythmical contractions at low volumes give rise to no sensation, but are more and more apt to intrude upon consciousness as the bladder wall becomes stretched.

Following a sudden lesion of the spinal cord or cauda equina there is paralysis of the detrusor vesicæ with tonic contraction of the internal sphincter. With recovery from the phase of spinal shock automatic micturition appears. In the case of a lesion of the cauda equina the volume of urine which the bladder will contain is small and expulsion is feeble. Following a lesion of the spinal cord which leaves the sacral segments and their connections with the bladder intact, the viscus is capable of greater distension and contracts more forcibly, and the act of micturition may be facilitated or inhibited by the elicitation of other reflexes dependent upon the isolated segments of spinal cord.

Defæcation. Denny-Brown and Robertson have also investigated the nervous control of defæcation and conclude that its mechanism is closely comparable with that of micturition. The main nerve supply to the rectum and anal canal, including the internal sphincter, is derived from the pelvic nerves arising from the second, third and fourth sacral roots. The nerve supply to the external sphincter is from the pudic nerves which also arise from the second, third and fourth sacral roots.

Automatic defæcation, however, can occur when the rectum and anus are cut off from these sources of nervous supply and must depend upon the function of reflex centres situated in the walls of the viscera. Tension upon the walls of the rectum results in muscular contraction with reciprocal relaxation of the internal sphincter. The whole process is involuntary, though it may be facilitated by voluntary contraction of the abdominal wall. Voluntary control of defæcation is limited to the action of the external sphincter, which can be opened or closed at will. When the central nervous connections of the rectum are intact, the reflex contractions show a progressive character and better fusion, so that the response to distension is more massive and more complete than it is when the

rectal plexus is cut off from central control. Following a lesion of the spinal cord or cauda equina there is a phase during which the rectal reflex is inhibited and the tone of the internal sphincter is increased. Following this, automatic defæcation is established, the loss of voluntary control being due to paralysis of the external sphincter.

Protective and Other Reflexes. Of the protective reflexes which are of importance in clinical investigation, the simplest is the *corneal reflex*—closure of the eye in response to a stimulus (tactile or otherwise) applied to the cornea. The reflex arc comprises on the afferent side branches of the trigeminal nerve. Most of the corneal surface is supplied by the ophthalmic division, but there is a small segment at the lower part of its circumference supplied by the maxillary. The efferent fibres are those branches of the facial nerve which supply the orbicularis palpebrarum. The corneal reflex may be diminished or lost in the case of lesions of the afferent or efferent fibres just described, or from lesions of the Gasserian ganglion, the sensory root or nucleus of the trigeminal nerve, or the nucleus or trunk of the seventh nerve.

Pupillary Reflex. The reflex contraction of the pupil to light is also in a sense a protective reflex. The afferent pathway comprises the retina, optic nerves and optic tracts, and the primary visual centres in the superior corpora quadrigemina. Hence, association fibres connect these afferent pathways from both sides with the cells responsible for innervation of the pupils which lie in the anterior part of the third nerve nuclei. Thus, both pupils contract in response to illumination of one eye. The reflex may be diminished or lost as the result of lesions of the retina, optic nerve, optic tracts, superior corpora quadrigemina, third nerve nuclei, or third nerves. In the case of a lesion of one optic nerve, illumination of the eye on that side will cause no contraction of either pupil, but illumination of the other eye will cause simultaneous contraction of both pupils. Under these circumstances, the pupil on the affected side is said to react to consensual but not to direct stimulation. The contraction of the pupils which occurs with ocular convergence and accommodation is an associated movement rather than a reflex.

Plantar Response. This is a reflex of great clinical importance. Under normal conditions in man stimulation of the sole of the foot by firm stroking contact causes flexion of the great toe. In the presence of a lesion of the pyramidal tract, this movement is reversed—the great toe moves upwards (extensor plantar response), and this movement is often accompanied by contraction of the flexor muscles of the lower limb as a whole. In the case of a complete transverse lesion of the spinal cord, after the phase of spinal shock is past, the contraction of the flexors is not confined to the limb whose sole is stimulated. Both lower limbs may be withdrawn simultaneously in a strong flexor spasm (mass reflex). The upgoing movement of the great toe and with it the flexor spasm of one or both lower limbs may be obtained from stimulation not only of the sole of the foot but from other areas, especially if the stimulus used is of noxious quality (scratching or pinching). The more complete the transection of the spinal cord, the wider the reflexogenous zone, and the greater the tendency towards a massive response, so that in the case of a complete lesion a dragged pin applied to any part of the lower limbs may provoke the mass reflex.

The character of this reflex, of which the extensor plantar response is a part, suggests that it is a protective movement of withdrawal. The reflex centres concerned lie in the lower part of the spinal cord. They are normally inhibited from above, and their activity is manifest only when the inhibitory influence is removed by disease.

The Abdominal Reflexes. Stimulation of the abdominal wall by stroking contact or a light scratch causes, under normal conditions, a brisk contraction of the underlying muscles. This probably has a protective origin, its purpose in the quadruped being to shake off flies. The reflex is lost when the afferent nerves from the skin or the motor nerves to the muscle are destroyed, and also when

foramina of Monro, the third ventricle and the aqueduct of Sylvius into the fourth ventricle, and so through the foramen of Magendie into the subarachnoid space, where it surrounds the whole of the brain and spinal cord. As the nutrient vessels enter the substance of brain and cord they invaginate the pia mater before them, and so there are formed around them perivascular spaces which are continuous with the subarachnoid space and contain cerebro-spinal fluid. There is some evidence to show that the fluid in these perivascular spaces plays the part of a medium of exchange between the blood and the nerve cells analogous to that played by the lymph in other structures of the body, and that the waste products of nervous metabolism are by this route drained into the cerebro-spinal fluid. The fluid obtained from lumbar puncture will therefore contain such waste products in addition to the pure secretion of the choroid plexus. The path of absorption of this fluid into the blood stream is by way of minute invaginations of the arachnoid membrane into the walls of the venous sinuses of the brain (arachnoid villi), and the rate of absorption is normally parallel with that of excretion.

As the result of disease, the outflow of cerebro-spinal fluid from the ventricular system may be obstructed, in which case that part of it which is proximal to the obstruction becomes distended. The expansion so caused may result in a great increase of the intracranial pressure.

LESIONS OF THE PERIPHERAL NERVES AND NERVE ROOTS

A lesion of one of the peripheral nerve trunks causes muscular weakness and wasting: loss of sensation—all forms being affected: and loss of reflex function. The distribution of these changes can be studied with the aid of diagrams. Lesions of the anterior or posterior nerve roots cause motor and sensory symptoms respectively, with loss of reflex function in both instances. The distribution of these also can be studied with the aid of appropriate diagrams and tables.

LESIONS OF THE SPINAL CORD

The results of a transverse lesion show themselves mainly as an interruption of the *conducting* power of the cord; but if the lesion is at all extensive vertically, its effects upon the *nerve-cells* must also be considered—*e.g.*, both upper and lower motor neurons are affected. The results also vary, according as the lesion is *bilateral* or *unilateral*, in consequence of differences between the motor and sensory fibres in the process of decussation.

Results of a Unilateral Transverse Lesion as Affecting Conduction (Brown-Séquard Syndrome)

On the same side as the lesion and below it.

Paralysis of muscles.

Hyperalgesia.

Loss of appreciation of posture of limbs, of passive movements, of separation of points applied to the skin, of size, shape, weight, and consistence of objects, and of vibrations of tuning-fork.

Tendon jerks at first lessened, then increased. Plantar reflex extensor, abdominal reflexes absent (if lesion high enough to affect them).

Vasomotor paralysis and elevation of temperature.

The sense of touch is retained, as well as sense of pain, heat and cold, the nutrition of muscles and their electrical reactions.

On the opposite side below

Loss of senses of pain, heat, and cold, and sometimes of touch.

Muscular power and nutrition, the muscular sense, reflex action, and temperature are normal.

Results of a Bilateral Transverse Lesion as Affecting Conduction

Anæsthesia below the level of the lesion.

Paralysis of all muscles below the level of the lesion ; there is no wasting ; the electrical reactions are not altered. Abdominal reflexes absent ; tendon jerks increased ; plantar responses extensor.

Loss of sphincter control.

These symptoms vary with certain conditions as follows : *if the lesion is of acute onset* there is at first, during the period of spinal shock, complete flaccidity of the paralysed muscles with abolition of tendon jerks and plantar responses. After a few weeks, *if the lesion is incomplete*, the paralysed limbs become spastic in extension with increased tendon jerks and extensor plantars. *If the lesion is complete* the paralysed muscles remain flaccid, but the lower limbs are subject to involuntary flexor spasms which may result in contracture ; the tendon jerks return : the plantar responses are extensor.

To these symptoms in each case may be added those caused by damage to the nerve cells of the particular segment affected, together with the motor and sensory fibres directly connected with it by the anterior and posterior nerve roots. These will naturally vary with the *level of the lesion*.

A *bilateral lesion of the upper cervical region* will produce spastic paralysis of all four limbs with sensory loss below the level affected. The local destruction of anterior horn cells will add to this, wasting and weakness of the sternomastoids and trapezii. Only patients with partial lesions at this level survive. A complete lesion causes paralysis of the diaphragm.

A *lesion of the cervical enlargement* will produce wasting and weakness of the muscles supplied from the segment affected, *e.g.*, in the case of the fifth cervical segment the deltoids, spinati, and biceps, with loss of the biceps tendon jerk (see Diagram, p. 594). Below the level of the lesion spastic paralysis and sensory loss.

In addition, all lesions above and including the first thoracic segment will produce paralysis of the cervical sympathetic fibres either in their downward course from the medulla, or at the point of their emergence in the first thoracic root (see Fig. 68, p. 606).

Lesions of the Thoracic Region produce little in the way of segmental signs. Nevertheless palpation may sometimes determine the presence of wasting and weakness of the intercostal muscles supplied by the affected segment. When the lesion is below the level of the eighth thoracic segment the upper halves of the recti abdominis are spared. Therefore the upper abdominal reflexes are preserved, and when the patient attempts to raise his head the umbilicus is pulled upwards by the unopposed action of the upper halves of the recti. As before, there will be sensory loss and spastic paralysis below the level of the lesion.

Lesions of the Lumbar Enlargement may be clinically divided according to their level as follows :—

Third and fourth lumbar segments : flexion of hip preserved ; apart from this lower limbs paralysed ; atrophy of quadriceps and adductors ; absent knee jerks ; brisk ankle jerks and extensor plantar responses.

First and second sacral segments : flexion of hip, adduction of thigh, extension of knee and dorsiflexion of foot preserved ; atrophy of calf muscles and intrinsic muscles of foot. Weakness of flexion of knee and extension, abduction and external rotation of hip. Knee jerks present ; ankle jerks and plantar responses absent.

Third and fourth sacral segments : paralysis of large bowel and bladder ; anal reflex lost.

Reference to the segmental sensory charts on p. 599 will indicate the extent of the sensory loss in each case.

Lesions of the Cauda Equina, when complete, may involve all the nerve roots

to use these muscles for the particular purpose of speech. Typically the man with a motor aphasia knows what he wants to say, but cannot say it.

Together with motor aphasia is usually associated *agraphia*, i.e. the patient is at the same time unable to express his thoughts in writing; and in certain rare instances the existence of agraphia has been recorded apart from aphasia in association with lesions of the second frontal convolution (Fig. 75).

In relation to aphasia may be considered *motor apraxia*, a condition in which without loss of power, sensibility or co-ordination the ability is lost to perform certain purposeful movements (such as brushing the teeth, lighting a match). This phenomenon has been observed after lesions of the upper left frontal convolution, of the upper part of the left parietal lobe, and of the corpus callosum, and is closely analogous to motor aphasia and agraphia, which may perhaps be considered as special types of apraxia.

Frontal Lobe. It has already been observed that the posterior part of the frontal cortex contains centres for rotation of head and eyes to the opposite side. A cortical lesion, therefore, may give rise to epileptic attacks, of which forced conjugate deviation may be the distinctive feature. On the left side a lesion situated far back and low down is likely to cause aphasia. A peculiar symptom met with in lesions of the upper and posterior part of the frontal lobe is known as forced grasping or tonic innervation in the opposite hand. The patient being asked to make a fist, or grasp an object firmly, is unable for the moment to open his hand again, this failure being due to persistent contraction of the muscles just innervated. This symptom, though rarely encountered, would seem to have a constant localising value. It is important in looking for it to make sure that the patient's inability to unclasp his hand on request is not due simply to confusion.

The remaining parts of the frontal lobe are relatively silent—that is to say, that lesions affecting them are not attended by any distinctive symptoms.

Parietal Lobe. On the left side, as we have seen, the parietal lobe is largely concerned with speech, while on both sides it contains the termination in the cortex of the sensory pathways. Through its lower part run the fibres of the optic radiation. The symptoms which are apt to result from a parietal lobe lesion, therefore, are sensory disturbance, homonymous defects in the opposite visual field, and on the left side aphasia. The postero-superior part of the parietal lobe, however, is relatively silent.

Temporal Lobe. The upper convolution contains the centre for hearing, but destructive lesions do not give rise to deafness, since the lower auditory centre on each side is connected with both sides of the brain. A lesion on the left side may encroach upon the speech area and is especially apt to cause difficulty in naming objects. The olfactory phenomena of the uncinat epileptic attack have already been described, and the fact has been mentioned that the optic radiation in a part of its course passes through the posterior part of the temporal lobe, so that homonymous field defects may play a part in the symptomatology of temporal lobe lesions. Nevertheless, a considerable lesion of the middle part of the temporal lobe, especially on the right side, may be silent.

Occipital Lobes. Lesions of the occipital lobe give rise to visual symptoms, which have already been described.

Silent Areas. There are many parts of the brain which may be destroyed or damaged by disease without the production of any symptoms of localising value. Indeed, it is surprising, in some cases, to see how much of the brain may be put out of action without any symptom at all.

Cortical lesions, elsewhere than in the specialised part already described, give rise to epileptic attacks of a generalised character, minor or major. Any extensive lesion of the white matter is liable to result in deterioration of the highest functions—such as impairment of the memory, especially for recent events, and changes for the worse in character and disposition. In the causation of such

symptoms, the amount of brain substance destroyed appears to be of more importance than its situation.

Basal Ganglia. Lesions of the basal ganglia are associated chiefly with motor disturbances such as rigidity and involuntary movements. Disease of the *corpus striatum*, especially the lenticular nuclei, results in a group of symptoms which, as they were originally described by Parkinson, in *paralysis agitans*, are frequently called Parkinsonian. There is rigidity of face, trunk and limbs which differs in quality from that seen in disease of the pyramidal tracts. The muscles yield slowly to passive movement (lead pipe rigidity) or in a succession of small jerks (cog wheel rigidity). Apart from the rigidity, there is slowness of movement, and there are involuntary movements taking the form of a regular rhythmic tremor, which is maximal in the extremities. The same group of symptoms may result from lesions of the *substantia nigra*.

A lesion of the sub-thalamic nucleus or nucleus of Luys results in involuntary movements of the opposite side of the body, including face, trunk and limbs, of the kind known as choreiform. These are jerky, purposeless contractions in various groups of muscles with no regular order or sequence.

Other types of involuntary movement, attributed with less certainty to disease of the basal ganglia, are those met with in athetosis and torsion spasm. In the former condition there are slow, writhing movements, which are most marked in the face and limbs. They are usually associated with some degree of rigidity of the pyramidal type and distribution. In torsion spasm, the movements are slow and massive, involving trunk and limbs in a more or less regular sequence, which produces the most violent contortions of the whole body.

The sensory disturbances which result from a lesion of or near the optic thalamus have already been described. Lesions in this neighbourhood are often associated with involuntary movements of the choreiform or athetoid variety.

Hypothalamus. This anatomical term includes the structures lying ventral to the optic thalamus, that is between it and the pituitary body, comprising the floor of the third ventricle, infundibulum and tuber cinereum. It has been shown by animal experiments that lesions in this situation may produce polyuria, obesity and pathological drowsiness, and similar effects are seen in tumours involving this area.

Corpora Quadrigemina. A lesion of these bodies causes vertigo, inco-ordination of the gait of cerebellar type and double ophthalmoplegia. The latter is of the nuclear type, and in the beginning may be limited to ptosis and paralysis of upward movement of the eyes, with which may be associated myosis and inactivity of the pupils. Deafness may also occur from involvement of the inferior corpora quadrigemina.

Crus Cerebri. Paralysis of the limbs on the opposite side and of the third cranial (oculo-motor) nerve on the same side is characteristic of a lesion of the cerebral peduncle at its inner and posterior part; this has been called the syndrome of Weber. Tremor of the opposite limbs with oculo-motor paralysis on the same side, or Benedikt's syndrome, is also due to a lesion of the crus cerebri. Gordon Holmes notes that lesions of the *mid-brain* (which includes the corpora quadrigemina and the crus cerebri, with the substantia nigra and red nucleus) have not infrequently been accompanied by definite, rather slow, tremors of the limbs.

Pons Varolii. This portion of the brain contains the pyramidal tracts, and the nuclei of the fifth, sixth, and seventh nerves. Large central lesions may paralyse all four limbs from the proximity of the two tracts to the middle line. A one-sided lesion in the upper part produces hemiplegia of the ordinary type on the opposite side of the body; but a lesion in the lower part, while involving the same pyramidal fibres for the arm and leg, is below the facial fibres for the opposite side, and destroys the facial nerve roots of its own side. There is then produced a variety of hemiplegia known as *crossed hemiplegia*, the

face being paralysed on the side of the lesion, but the arm and leg on the opposite side. A lesion involving the nucleus of the sixth nerve on one side will give rise not only to paralysis of the external rectus on this side, but also to paralysis of the internal rectus of the opposite eye in attempted conjugate deviation of both eyes towards the side of the lesion.

Medulla. Any extensive disease in this neighbourhood is incompatible with life owing to involvement of the vital centres. A unilateral lesion causes weakness of the tongue and palate on the same side and motor and sensory loss on the opposite side of the body. With this may be associated motor inco-ordination on the side of the lesion from involvement of the cerebellar tracts, and also on the same side miosis and enophthalmos from involvement of the cervical sympathetic centre (*see* p. 606).

Cerebellum. The main afferent pathways to the cerebellum are the dorsal and ventral spino-cerebellar tracts, which convey impulses from the muscles and joints: fibres from the vestibular nuclei, which convey impulses from the labyrinths: and a large number of fibres from each cerebral hemisphere, which descend on either side of the pyramidal fibres in the corresponding half of the mid-brain (fronto-pontine and temporo-pontine tracts), end in the pontine nuclei, and thence are connected with the cortex of the opposite lobe of the cerebellum. The main efferent pathway from each lobe of the cerebellum is through the superior cerebellar peduncle, which crosses the mid-line to end in the opposite red nucleus. From the red nuclei arise the rubrospinal tracts which decussate shortly after their origin, and end in connection with the anterior horn cells of the spinal cord. On the efferent side, therefore, each lateral lobe of the cerebellum is, by means of this double decussation, connected with the lower motor neurons of its own side of the body. It receives impulses from the muscles of its own side, and from the cerebral hemisphere of the opposite side. The impulses derived from the labyrinths appear to be destined mainly for the middle cerebellar lobe.

Lesions of the cerebellum in man cause inco-ordination of voluntary movements, disturbances of posture and gait, and nystagmus. The most important symptom of a lateral lobe lesion is inco-ordination of the limbs on the same side. Although there is no loss of power, or ability to initiate movement, the working together (synergy) of the different muscle groups is defective. The result is disorder in the inception, progress and termination of willed movements, especially those in which large numbers of muscles are involved, or in which rapid alternation is required between opposing muscles. The disorder of function is more apparent in the upper than the lower limb. Asked to touch his nose with the tip of his forefinger, and then to touch the tip of the observer's finger, and to continue this alternation as rapidly as he can, the patient shows zig-zag deviation from the line of movement, particularly as his finger nears the target, and a tendency to under-shoot or over-shoot the mark. The limbs on the same side as the lesion are often hypotonic, the occiput as in labyrinthine lesions tends to fall towards the shoulder on the side of the lesion, and in walking the patient deviates or staggers towards the same side. The eyeballs tend to drift towards the opposite side of the midline so that nystagmus is obtained when the patient is asked to look towards the side of the lesion.

In lesions which are confined to the middle lobe of the cerebellum all the symptoms which have been described may be lacking, the outstanding clinical feature being an unsteady reeling gait, with no particular tendency to deviate or stagger towards one side or the other.

CLINICAL EXAMINATION OF THE NERVOUS SYSTEM

In the examination of the nervous system it is convenient to proceed according to a regular plan, which enables the observer to make a rapid survey of the case.

In the course of such a survey points will be noted which call for more detailed examination of particular functions, methods for which will be described in the text under the appropriate headings. The subjoined scheme is intended to serve as a practical guide to routine examination; the smaller type denotes points which are not considered essential in the absence of special indications for their use.

SCHEME FOR ROUTINE EXAMINATION OF THE NERVOUS SYSTEM.

1. Cerebral function.
 - Intelligence.
 - Temperament.
 - Speech.
2. The special senses.
 - (a) Vision.
 - Acuity.
 - Fields of vision.
 - The fundus oculi.
 - (b) Hearing.
 - (c) Smell.
 - (d) Taste.
3. The cranial nerves.
4. Sensory functions.
 - Sensibility to cotton wool.
 - Sensibility to pin prick.
 - Sensibility to temperature.
 - Sense of position.
 - Sensibility to vibration.
 - Stereognosis.
5. The motor system.
 - Involuntary movements.
 - Atrophy or hypertrophy.
 - Tone.
 - Power.
 - Co-ordination.
 - Electrical reactions.
6. The reflexes.
7. Sphincter control (urethral and anal).
8. Trophic changes.
9. Posture and gait.
10. Cerebro-spinal fluid.

1. CEREBRAL FUNCTION

Intelligence. A fair measure of the patient's intelligence may usually be made from the manner in which he gives the history of his illness. If the intellectual functions appear to be defective, further examination should be made. In estimating powers of memory for the remote past, it is important to compare the patient's account of his life with that given by friends or relations. Memory for the recent past may be tested by asking the patient to give an account of the past twenty-four hours, and it is important to make sure that he is correctly oriented as to date, place and persons.

Temperament. Variations from the normal may appear in the form of dominating moods of depression or elation, or as emotional instability. Such variations are most commonly met with in cases of functional nervous disease, in which further questions should be directed to the investigation of special pre-

occupations or troubles, and inquiry made as to the presence of imaginary ideas, feelings of inadequacy, obsessions or feelings of compulsion.

Speech. This may be affected by lesions at a high or a low level, the resultant disturbances of function being known as aphasia and dysarthria respectively. Aphasia means a partial or complete loss of the ability to comprehend ideas conveyed by words, or of the power of verbal expression. Dysarthria implies a defect in verbal articulation due to weakness or inco-ordination in the muscles involved.

The presence of aphasia will be detected in the course of obtaining the patient's history, and should be further investigated along the following lines :—

1. Can the patient understand spoken words? Give him at first simple commands such as "Put out your tongue," proceeding to more complex directions, such as "Touch your right ear with the middle finger of your left hand."

2. Can he understand written words? Give him similar commands in writing, first in block capitals, then in ordinary handwriting.

3. Can he spontaneously utter intelligible words?

4. Can he write spontaneously?

Failure in test 1 alone would indicate a pure word-deafness, in test 2 alone a pure word-blindness. These two conditions are very rarely met with as a result of minute lesions of the incoming auditory or visual paths to the speech centre. More commonly there is failure in both tests as part of general sensory aphasia.

Failure in test 3 alone indicates pure motor aphasia, in test 4 pure agraphia. These two functions also are most commonly lost together.

The patient with motor aphasia from a lesion of the foot of the inferior frontal convolution can understand reading and writing, and his intelligence is therefore unimpaired. He is rarely dumb, but his vocabulary is reduced, sometimes to a few very simple words, such as "Yes" and "No," whether he tries to express himself vocally or in writing. He is, of course, conscious of his own disability and its nature.

The patient with sensory aphasia, in addition to his failure of comprehension, also shows errors in the expression of speech, since his word-blindness and word-deafness render him unable to test the correctness of the words he is writing or uttering, a process which is apparently an essential adjunct to the mechanism for outgoing speech. He may talk fluently enough, but tends to mix up words and syllables, and may produce an unintelligible jargon, similar defects being shown in writing. He will naturally make mistakes in reading aloud, writing to dictation, or repeating words heard.

There appears to be a special tendency simply to forget the names of people and things, and to be unable to name objects seen, in lesions of the posterior part of the temporal lobe.

It is important to find out in a case of aphasia whether the patient is left-handed, and if not whether left-handedness is hereditary in his family.¹ Aphasia is found in lesions of the left side of the brain in right-handed people, and *vice versa*; a right hemiplegia, if severe, is nearly always accompanied by aphasia, which is greater in proportion to the degree of paralysis of the arm.

(For further details as to the localisation of speech function *see* p. 614.)

Dysarthria. Since the muscles involved in articulation are innervated from both hemispheres, it is only when there is a lesion of the cortico-bulbar path on each side that an *upper neuron* lesion gives rise to paralytic dysarthria. This condition occurs in multiple vascular or syphilitic lesions of the brain, being commonly accompanied by emotional instability and a severe degree of mental impairment. It is called pseudo-bulbar palsy to distinguish it from the dysarthria caused by lesions of the *lower neurons*, *e.g.* that met with in progressive muscular atrophy affecting the medulla. Speech in all these cases is clumsy, as if

¹ Foster Kennedy has shown that in a right-handed person of strongly left-handed stock the speech centres may be situated in the *right* hemisphere, and *vice versa*.

the patient had a hot potato in his mouth, and in true bulbar palsy the patient sometimes becomes completely anarthric.

Dysarthria may also result from a disturbance of the cerebellar co-ordinating mechanism, as in disseminated sclerosis and in some cases of cerebellar lesions (p. 718).

The above forms of dysarthria become apparent when the patient is giving his history, but in a suspected case of dementia paralytica in which the articulatory defect may be due partly to loss of power, partly to loss of co-ordination, and may be an early sign, it is useful to enjoin upon the patient the pronunciation of certain test phrases, such as "Methodist Episcopal," "West Register Street," etc. The defects to be looked for are slurring, elision of syllables or transposition of syllables or words.

2. SPECIAL SENSES

Vision. *Acuity.* In default of regulation test type, the acuity of vision may be roughly tested by getting the patient to read aloud from small print with each eye in turn; if acuity is poor, allow him to wear glasses if he has them; if these are correct, and the defect lies only in an error of refraction, his visual acuity should be normal with glasses.

Visual Fields. These may be roughly tested as follows: The patient places a hand over his right eye, and fixes the gaze of the other upon the pupil of the observer's right eye; the observer himself closes his left eye, and fixes his attention upon the patient's left eye; he then takes a small white object upon a handle—the most convenient is an ordinary white-headed hat-pin—and holding it midway between himself and the patient, brings it in gradually from the periphery towards the centre of the visual field, instructing the patient to say "Now!" when he sees it. In this way the observer can compare the field of each of the patient's eyes with his own and can discover defects of any considerable size. Examination of the visual fields is a most important procedure, and may lead to valuable discoveries, especially in the case of lesions affecting the optic tracts (*e.g.* pituitary tumour) or optic radiations (*e.g.* a vascular lesion at the posterior end of the internal capsule) (*see* p. 611).

Fundus Oculi. For the physician the eye is the window of the brain, and the electrical ophthalmoscope renders examination of the optic disc so easy that it should be made in every case in which nervous disease is suspected. The main changes to be looked for in the disc are œdema and atrophy.

Papillœdema is usually the result of increased intracranial pressure, and the mechanism of its production is discussed later (*see* p. 634). In a typical early case the central vein is engorged, the physiological cup filled in with exudate, and the edges of the disc, instead of being clear-cut, are hazy; later the œdema may be such as to give the disc a "chrysanthemum-head" appearance, and there are patches of exudate and hæmorrhages in the retina surrounding the disc.

In *optic atrophy* the disc appears paler than normal, and in an advanced stage of the condition stands out a dead white against the surrounding pink retina. The minute appearances vary somewhat with the cause and are discussed later (*see* p. 635).

It is important to realise that, while optic atrophy is always associated with some defect of visual acuity, the presence of an advanced papillœdema is consistent with the preservation of normal vision, and it is not until the swelling begins to subside and the condition passes into one of secondary atrophy that acuity becomes diminished. Other evidence of value may be found in some cases of brain disease from an examination of the retinal arteries, whose condition is perhaps the best index of that of the cerebral arterioles. In cases of cerebral arteriosclerosis the retinal arteries are often tortuous and thick-walled, nipping the veins where they cross them; there may also be visible beading of the

any one of the muscles which turn the eye inward the images seen by the two eyes will be crossed; *i.e.* if the right eye be closed the left-hand image will disappear, and *vice versa*: while in paralysis of the muscles which move the eye outward the images will be uncrossed; *i.e.* if the right eye be closed the right-hand image will disappear. In the case of the muscles which move the eye obliquely the false image will also appear tilted at an angle to the true image depending (Fig. 76) upon the muscle involved.

The accompanying chart, devised by Bishop Harman, shows (1) the movements of the ocular muscles; (2) the position of the false image in paralysis. It should be remembered that in certain diseases, *e.g.* disseminated sclerosis and syphilis of the nervous system, ocular palsies may occur which are of very brief duration. It is therefore important in taking the history of a case of nervous disease to inquire for transient diplopia.

In the course of testing the ocular movements the examiner will note the presence or absence of *nystagmus*. This is a condition in which conjugate movements of the eyes are poorly sustained, and in place of a steady deviation we see a succession of jerky oscillations. These may be slow or quick, coarse or fine, lateral or rotatory.

It should be remembered that in persons weakened by old age or constitutional disease prolonged deviation of the eyes in a single direction will readily cause fatigue of the ocular muscles, and so give rise to oscillatory movements somewhat resembling those of *nystagmus*.

The Fifth, or Trigeminal Nerve. The distribution to the skin of the three branches of the sensory division of this nerve is shown in Fig. 66.

Sensibility to cotton wool, pin prick, and heat and cold over this area may be tested as presently to be described in relation to the other cutaneous areas. The buccal and nasal mucous membranes of the corresponding side are also supplied by each nerve. The earliest objective sign, however in lesions of the sensory root or its ophthalmic division is a diminution or loss of the corneal reflex on the affected side. This sign may be sought as follows: The patient is directed to fix his vision on some object to his extreme left, while the observer, standing a little behind him on his right, brings a wisp of cotton wool into light contact with the right cornea in such a manner that the object is felt before it is seen. The process is repeated for the left cornea, and the threshold for the blinking reflex on the two sides is thus compared.

The motor branch of the fifth nerve supplies all the muscles of mastication. In paralysis of this branch, when the patient's teeth are tightly clenched the observer by placing his thumbs against the anterior borders of the two masseter muscles can detect the weakness on the affected side, and when the mouth is opened wide the point of the jaw is deflected towards the paralysed side.

Subjective sensations of numbness, tingling, or pain in one or more of the areas supplied by the sensory root may precede objective phenomena in lesions of this nerve.

The Seventh, or Facial Nerve. In complete paralysis of this nerve the affected side of the face is mask-like, immobile, and expressionless; the naso-labial fold is smoothed out; the wrinkles disappear from the forehead; the eye is wider open than on the sound side; and the corner of the mouth hangs downwards.

The patient may complain of irritation of the conjunctiva on the affected side (owing to loss of the blinking reflex from paralysis of the orbicularis palpebrarum) as well as a certain clumsiness in speaking. Lesser degrees of weakness may be detected by requesting the patient to close his eyes tightly and show his teeth at the same time, a procedure which usually unmasks any asymmetry that may be present. The patient is also made to open his mouth widely, which brings the naso-labial grooves into prominence, when they may be compared.

The Eighth Nerve. The examination of the auditory functions of this nerve has already been described under the Special Senses. In cases of vertigo,

or of nerve deafness, in which it is desirable to investigate the vestibular functions, a simple method is as follows: The patient is made to stand up and turn rapidly round five times, first clockwise and after a short rest counter-clockwise. Immediately after the last turn in the clockwise direction (*i.e.* from his left to his right) he is made to fix his gaze on a point to his extreme left, and after turning in the opposite direction on a point to his extreme right. In each case transient nystagmus should be observed, and if the function of both vestibules is normal, the rapidity of the movements of the eyes and their duration should be the same when the individual is rotated clockwise or counter-clockwise.

The Ninth, or Glosso-pharyngeal Nerve. This nerve supplies sensory fibres, the posterior third of the tongue and the soft palate, and motor branches to the pharynx. The sensory function may be tested with a wisp of cotton wool fastened to the end of a probe.

The Tenth Nerve, or Vagus. The simplest objective test for the vagus is to ask the patient to say "Ah!" and watch the palate. Normally one sees the median raphe of the soft palate rise straight up, but if one side be paralysed, the healthy side alone pulls upwards, and the raphe deviates to the sound side, forming a characteristic dimple.

(For further symptoms *see* p. 640.)

Eleventh, or Spinal Accessory Nerve. In order to test the function of this pair of nerves, which are purely motor, one asks the patient to shrug his shoulders, which is effected by the trapezii, and then to flex his neck against resistance, which brings both sternomastoids into play in such a manner that the contractions of the two muscles may be easily compared.

Twelfth, or Hypoglossal Nerve. This nerve also is purely motor in function, supplying the tongue and most of the muscles attached to the hyoid bone. To investigate its function one asks the patient to protrude his tongue. In bilateral paralysis there is no movement; in cases of unilateral paralysis the tip of the tongue is pushed over towards the side paralysed by the sound muscles on the other side. If the paralysis is due to a lower motor neuron lesion (*i.e.* of the nuclei or fibres of the hypoglossal nerve), there is atrophy of the muscles on the affected side, and the superjacent mucous membrane is thrown into wrinkles.

4. SENSORY FUNCTIONS

Sensibility to Light Touch. The patient is asked to say "Yes" each time he appreciates the touch of a wisp of cotton wool or a camel's-hair brush. The examiner begins with a few touches over areas of skin not suspected of being anæsthetic, and if contacts are missed in other regions, applies the stimulus again to the normal areas from time to time to ensure that the failure to respond is not due merely to lack of attention.

The sensitiveness of the limbs is first explored by means of a few touches applied to each hand and foot; the investigation should then be carried longitudinally up each limb, and finally a series of stimuli should be applied, following the circumference of the limb at one or two levels. This will ensure that a small area of segmental anæsthesia is not missed. The skin area of the trunk is investigated in a similar manner. If a zone is discovered in which sensation appears to be lost or blunted, this must be carefully tested, and the resultant area of anæsthesia outlined in blue pencil on the skin, from which it may be copied on to a chart.

The investigator should not be content with an objective examination, but should direct the patient to inform him if at any point the stimulus appears relatively less distinct than in normal areas, and should especially inquire whether touch is appreciated equally on both sides of the body.

Sensibility to Pain is investigated along similar lines, the point of an ordinary pin being employed as stimulus. Here again it is most important to discover from the patient any quantitative diminution of sensation.

Kernig's Sign. In meningitis and some other conditions it is found that if the thigh be flexed at a right angle with the body, either by placing the patient in a sitting posture or by raising the thigh vertically while the patient is recumbent, it is impossible to extend the leg on the thigh to the same extent as usual, in consequence of the contraction of the hamstring muscles (see Fig. 77). The muscular spasm in this case is mainly due to a voluntary contraction whose object is to ward off the pain caused by stretching inflamed nerves or nerve roots.

Voluntary Power is systematically investigated by asking the patient to perform various movements against resistance, flexion and extension of the fingers, wrists and arms, pronation and supination, and so on.

In case of weakness due to a lesion of pyramidal fibres the muscles most affected are in the upper limb the extensors, with earliest loss of power in movements of the fingers and extension of the wrist, and in the lower limbs the flexors, with earliest involvement of dorsiflexion of the foot.

Inco-ordination of movement in the absence of weakness may be due to loss of sense of position and passive movement. This is best called ataxia in order to distinguish it from the inco-ordination of cerebellar disease, though the latter is sometimes spoken of as cerebellar ataxia. Many methods have been devised for testing co-ordination, of which the simplest and best are as follows :—

Finger-nose-finger Test. The observer holds up his right index finger in front of the patient and within his reach. The patient is instructed with the tip of his right index finger to touch first the end of his own nose, then the tip of the observer's finger, and to repeat these movements alternately as quickly and as neatly as possible. The observer meanwhile changes the position of his finger in relation to the patient between the contacts.

Inco-ordination is revealed by deviation from the line of movement with clumsiness and delay in arriving at the mark, and by a tendency either to stop short of it or overshoot it (dysmetria).

Diadochokinesis Test. The patient holding his arms semiflexed with the elbows to his sides, and fingers clenched, performs alternate movements of pronation and supination simultaneously with both forearms as rapidly as possible.

Inco-ordination is revealed by dysdiadochokinesis; the affected limb lags behind its fellow; its action is clumsy and unbalanced, and is made to appear more so by superfluous movements at the elbow and shoulder.

The Heel-knee Test. The patient in the recumbent position lifts one heel high into the air, places it gently upon the opposite knee and slides it steadily down the anterior border of the tibia as far as the ankle. This series of movements should normally be performed smoothly and evenly. Inco-ordination is revealed by unsteadiness and irregularity.

Electrical Reactions. The nature of the response of a muscle to electrical stimulation is sometimes of value in distinguishing between the different causes of paralysis, and in determining the moment at which recovery begins after a lower motor neuron lesion.

The student is presumed to be familiar with the methods of physiological application of the electric current to the stimulation of muscle and nerve, which are to be found in the text-books of physiology.

The faradic current is an adequate stimulus to nerves and nerve endings, and when applied to normal muscles in health provokes a brisk and well-sustained contraction, which is especially well marked if the electrode is placed over the point at which the motor nerve enters the muscle.

In the case of a complete lower motor neuron lesion there is no response to faradic stimulation either of the nerve or muscle involved; in the case of incomplete lesions there may be a quantitative diminution of the response.

To the galvanic current muscular contraction is only obtained when the circuit is closed and opened; none is observed during the continued flow of the current.

As there are two poles, four series of contractions may be observed, two on opening and closing the circuit where the stimulating electrode is the kathode and two on opening and closing the circuit when the anode is used as the stimulating point.

These are usually represented by letters as follows :—

K.C.C. = Kathodal closing contraction.

A.C.C. = Anodal closing contraction.

A.O.C. = Anodal opening contraction.

K.O.C. = Kathodal opening contraction.

In health, galvanic stimulation is effective whether applied to the muscle or the nerve, resulting in a short sharp contraction. If the strength of the current be constant and moderate, it is found that K.C.C. is greater than A.C.C.

In the case of a lower motor neuron lesion galvanic stimulation of the nerve no longer produces a response. The muscle, however, shows certain changes in its response, which are described as the reaction of degeneration (R.D.).

Qualitatively the response to galvanism is slow and sluggish, instead of short and sharp, and quantitatively it is found that with a constant strength of current A.C.C. is equal to or greater than K.C.C.

The return of faradic excitability in a muscle is usually the earliest sign of recovery from a lower motor neuron lesion.

In certain diseases, Thomsen's disease and myasthenia gravis, there may be characteristic changes in the electrical excitability, which are described under these headings.

6. THE REFLEXES

The reflexes are divided into superficial, deep, and visceral. Their presence depends upon the integrity of the sensory and motor end organs and the afferent and efferent paths involved in the reflex arc. They may also be modified by destructive lesions of higher centres, which have a controlling or inhibitory influence over them.

The reflexes of chief value in clinical examination are the following :—

Superficial Reflexes. The pupillary, corneal and pharyngeal reflexes are described under the Cranial Nerves. The abdominal reflexes are obtained by light stroking of the skin, with resultant contraction of the underlying musculature. There may be distinguished an epigastric mid-abdominal and lower abdominal reflex on each side. These are present and equal on the two sides in the great majority of healthy adults. They may, however, be absent when the abdominal wall is loose and pendulous, as in a multipara, in cases of intra-abdominal disease, such as typhoid, and when the patient is unduly cold.

Their absence, apart from these causes, implies an affection of pyramidal fibres ; the abdominal reflexes are lost on the opposite side of the body when the lesion is above the pyramidal decussation, on the same side if below it. Loss of these reflexes is frequently an early sign of pyramidal involvement, and a constant quantitative difference between the responses obtained on the two sides of the body may be of value in diagnosis in cases where there is no absolute loss. The cremasteric reflex is obtained by stroking the skin along the inner surface of the thigh ; the response is drawing up of the testicle. Together with the abdominal reflexes, it is lost in the affected side in cases of pyramidal lesion.

The Plantar Reflex. In conditions of health stroking the outer margin of the sole of the foot produces flexion of the small toes and of the great toe at the metatarso-phalangeal joint. This response may be complicated in ticklish persons by voluntary movements of withdrawal or rigidity due to apprehension. For the elicitation of the test it is best to have the lower limb lying passively extended. The skin should be warm and dry. The nature of the optimum stimulus depends in each individual case upon a number of variable factors. As a rule, firm pressure with the thumbnail drawn slowly from the heel towards the base of the toes along the outer border of the sole is sufficient, or a blunt-pointed instru-

ment may be used. The reflex response is lost in lesions of the reflex arc of the first sacral segment ; in coma ; with the sensory disturbances involving the sole foot in tabes ; with paralysis of the toe muscles, as in acute poliomyelitis ; and when the feet are cold. In the presence of a lesion of the pyramidal fibres, in place of the normal response Babinski's sign is elicited on the corresponding side ; this consists of an upward movement of the great toe, with abduction and fanning of the others, and is accompanied by a contraction of the hamstrings. In cases of complete transverse lesion of the cord there ensues at first loss of the plantar responses, but with recovery from spinal shock there develops a mass movement of withdrawal of both limbs in response to stimulation of the sole of either foot.

Deep Reflexes. These are true reflexes, the activity of which is an indication of the state of the muscular tone, while their presence depends upon the integrity of the reflex arcs and end organs concerned.

They are tested by placing the limb in such a position as to relax the muscle whose tendon jerk is to be elicited. The observer then puts the muscle under slight tension and gives the tendon a sharp tap with a percussion hammer. The response is a contraction of the muscle and movement of the part. The deep reflexes of most clinical value are the following :—

The Triceps Jerk. This is obtained by semiflexing the arm at the elbow and striking the tendon just above its insertion into the olecranon.

The Biceps Jerk is obtained by flexing the elbow joint, placing the thumb upon the biceps tendon just above its insertion and slightly stretching the muscle. The thumb is then struck, and the biceps contracts.

The Supinator Jerk. To obtain this, the observer holds the patient's hand loosely with elbow semiflexed and forearm semi-pronated, and strikes the outer border of the radius just above the styloid process. The response is a contraction of the supinator longus (brachio-radialis) flexing the elbow.

The Knee Jerk. With the patient lying on his back, the observer, supporting the knee from beneath in a position of slight flexion, strikes the ligamentum patellæ sharply with the hammer. The result is a brisk contraction of quadriceps femoris. The knee jerks may equally well be obtained with the patient sitting in a chair and having one leg crossed over the other. It is essential that the limb should be fully relaxed. If the reflex is not elicited then, the patient's attention should be distracted, as by getting him to hold the fingers of one hand in those of the other, and to look up to the ceiling while he pulls at his hands (*Jendrassik's reinforcement*).

The Tendo Achillis, or Ankle Jerk. This is obtained by putting the calf muscles slightly on the stretch and tapping the tendo Achillis, the response being a brisk contraction of the muscles.

Ankle Clonus. *Ankle clonus*, or *foot clonus*, is a similar phenomenon, which occurs in certain spinal and other diseases, but is not, like the knee jerk, present in health, except in a modified form. To elicit it, the patient should be seated or recumbent ; the leg is lifted with the left hand under the knee, so that the knee is slightly bent, and the foot, held firmly by the toes in the right hand, is sharply bent towards the knee. Immediately the calf muscles contract, but as the pressure on the foot is maintained, they relax, again contract, and so alternately contract and relax for an almost indefinite period, constituting the so-called *clonus*. The contractions occur at the rate of about seven in a second. The modification of this phenomenon which occurs in health is the series of rapid alternating movements which can be kept up continuously and without effort when, in the sitting posture, the foot rests upon the ground by the toes only.

A *knee clonus* can be sometimes obtained either as a result of percussing to get the knee jerk, or by pushing the patella down towards the tibia, while the leg is extended on a couch.

Exaggeration of the deep reflexes and ankle clonus are found together with absent abdominal reflexes and Babinski's sign as the result of pyramidal lesions. Loss of the tendon jerks may result from disease of the muscles, peripheral nerves, anterior or posterior roots, or anterior horn cells.

Quantitative alterations of the tendon jerks are of value when there is a marked difference in vigour between, for instance, the knee jerks and the ankle jerks, or between the responses obtained on the two sides of the body.

The state of the deep reflexes in general, however, may be influenced by many conditions, such as emotional excitement, fatigue, temperature and intoxication.

7. SPHINCTER CONTROL

The Bladder. Apart from obvious retention or incontinence of urine, the patient should be questioned with regard to a history of difficulty in commencing micturition or the more common fault of being unable to delay the act once conscious of the need (precipitate micturition).

The Rectum. The early symptoms of paralysis affecting this part are constipation, or more truly dyschezia (*see* p. 357), and when recourse is had to purgatives difficulty in controlling a loose motion, with occasional soiling of the garments.

8. TROPHIC CHANGES

The nutrition of the tissues is profoundly affected in some diseases of the nervous system, but there is no evidence of separate trophic nerves or neurons. The most marked effects are seen in lesions of nerve trunks and their centres, *i.e.*, those which injure the lower neurons, motor and sensory. Thus lesions of the anterior cornua (acute poliomyelitis) or of the nerves (injury, neuritis) are accompanied by marked wasting of muscle, which is not present in lesions of the brain or cord, involving the upper neurons only. Wasting of muscle is first shown by flabbiness, later by actual diminution in size. Its extent can be estimated by measurement, but it must be remembered that subcutaneous fat may completely mask a good deal of wasting so far as bulk is concerned. Other parts besides the muscles are often involved. The skin in some chronic cases becomes thin, red, and shiny—the “glossy skin” of Paget; erythematous, bullous, and vesicular eruptions (*e.g.* zona), œdema, whitlows and ulceration of the skin may occur; the finger nails are pinched, from wasting of the subcutaneous tissue; the growth of hair and nails is retarded; and the nails are brittle. The bones may also suffer in their nutrition, becoming brittle or breaking easily; and if paralysis occurs in early life, growth of a whole limb may be retarded, so that it is eventually $1\frac{1}{2}$ to 2 inches shorter than its fellow. In acute cases the temperature of the skin is raised, the vessels dilate, vesicles or bullæ form, and bedsores occur on the slightest irritation or pressure.

9. POSTURE AND GAIT

If the patient is not bedridden, he should be made to walk up and down the room in his ordinary manner, and any peculiarity of his carriage or gait should be noted. The changes characteristic of various lesions are described under other headings. It should be noted here that account must be taken of skeletal deformities and disease of joints, and further that weakness of certain groups of muscles (*e.g.* the hamstrings and glutæi) may lead not only to abnormalities in the gait, but also to the adoption of certain postures calculated to preserve the centre of gravity in the appropriate position.

10. CEREBRO-SPINAL FLUID

Examination of the cerebro-spinal fluid in disease often yields information of the greatest value in diagnosis. This fluid, as obtained by lumbar puncture, is

normally clear and colourless, and contains a trace of sugar sufficient to reduce Fehling's solution.

Pressure. Increased pressure of the fluid may be due to acute inflammatory changes in the meninges, with consequent outpouring of exudates into the sub-arachnoid space, or to increased intracranial pressure, as in cases of cerebral tumour. Variations in the intracranial pressure are under normal conditions transmitted through the fluid surrounding the spinal cord to the site of lumbar puncture, and if a manometer be attached to the needle these variations may be measured. The normal pressure with the patient in the lying posture varies from 60 to 150 mm. of water. A pressure above 200 mm. indicates a pathological increase of intra-cranial pressure. In a normal person digital compression of the jugular veins causes a sharp rise in the cerebro-spinal fluid pressure. The absence of such a rise indicates an obstruction in the spinal subarachnoid space, and is sometimes a useful point in evidence of compression of the spinal cord by growth or inflammation.

Blood in the spinal fluid taken for examination may come from a vein accidentally wounded at the moment of lumbar puncture. It may, on the other hand, be an indication of hæmorrhage into the subarachnoid space. A useful point of distinction is that blood from an accidental source, if left to stand, will coagulate in the test tube, leaving a colourless supernatant fluid. In the case of a pre-existing subarachnoid effusion coagulation will probably have taken place already at the site of hæmorrhage, and some hæmolysis will also have occurred. If the blood-stained fluid is allowed to stand the red cells settle to the bottom of the tube without the formation of a clot, and the supernatant fluid is coloured yellow or brown from the presence of altered blood pigment.

Bacteriology. In cases of acute infective meningitis the causal organism may often be seen in smears, and may nearly always be grown from cultures. When tuberculous meningitis is suspected the bacillus should be sought for and is often found, or the fluid may be injected into a guinea-pig.

Cell Content. The number of cells per cubic millimetre is of great importance. The normal value is below 3; any rise above this figure must be considered pathological, and is usually evidence of acute or chronic inflammatory changes in the meninges.

In cases of acute meningitis due to the meningococcus, pneumococcus, streptococcus, etc., the increase is in polymorphonuclear leucocytes, which are often sufficiently numerous to give the fluid a turbid appearance.

In tuberculous meningitis the majority of the cells are lymphocytes, usually in large numbers.

In acute poliomyelitis during the first week of the illness there is an excess of lymphocytes varying from 15 to 100 per cubic millimetre, and in encephalitis lethargica there appears to be a similar increase in the majority of cases.

In the various forms of cerebro-spinal syphilis there is an almost constant increase in the number of lymphocytes, ranging from figures just above the normal to 200 or 300 per cubic millimetre, the number depending upon the stage of activity of the disease and the degree of meningeal involvement.

An excess of lymphocytes may occasionally accompany a tumour of the brain or cord.

Protein Content. This may be roughly estimated on a quantitative scale by precipitation by boiling 2 c.c. of the fluid with 0.3 c.c. of 30 per cent. trichloroacetic acid and comparing the density of the coagulum with that of standard tubes containing known percentages of albumin precipitated in the same way. The normal content is 0.025 per cent. This is increased in fluids from patients with acute infective meningitis as a rule to about 0.3 per cent., sometimes higher. In cerebro-spinal syphilis there is nearly always an increase, though the figure is not as a rule higher than 0.10 per cent. There is also a moderate increase in the other diseases enumerated in which raised cell counts

are found. A raised protein content is also encountered in certain cases of cerebral tumour and in polyneuritis.

The highest amounts of protein, however, are found in compression of the spinal cord. When, from any cause, the subarachnoid space is completely occluded at a level above that at which lumbar puncture is performed, the fluid obtained from the lower secluded sac has certain definite characteristics. It is clear, of a golden yellow colour, contains an enormous excess of albumin—up to 4 per cent.—and fibrin, so that it undergoes massive spontaneous coagulation. This is known as *Froin's syndrome*. The presence of simple excess of albumin in quantity greater than that met with in other conditions, without the golden colour or fibrin, may precede the appearance of the Froin syndrome, or appear as a stage in its retrogression.

The occlusion of the subarachnoid space may be due to disease of the vertebræ (caries or growth); fibrinous or cicatricial adhesions of the meninges, as after an acute meningitis or in syphilis; or the growth of a tumour from one of the meninges or within the cord. The cerebro-spinal fluid obtained from above the level of the block shows in every case a relatively normal appearance and albumin content. The Froin syndrome may be produced experimentally in animals by artificial compression of the cord with subdural injections of paraffin wax.

The cell count in Froin's syndrome depends on the pathological nature of the compressing cause, being high in the case of syphilis, low in all other cases.

Chlorides. The percentage of chlorides in normal cerebro-spinal fluid is constantly between 0.70 and 0.76 per cent. (NaCl). This may be slightly lowered in acute general infections, but a figure below 0.68 per cent. as a rule indicates meningitis. The lowest percentages are found in tuberculous meningitis, in which a figure of 0.60 per cent. or less is common. The point is, therefore, of considerable value in differential diagnosis.

The estimation is made by titration with standard silver nitrate, using potassium chromate as an indicator. Two cubic centimetres of cerebro-spinal fluid are required for the examination.

Wassermann Reaction. This is positive in the cerebro-spinal fluid at an early stage in every case of dementia paralytica, and in the great majority of active tabetics.

As regards cases which show clinical evidence of meningo-vascular syphilis the reaction is positive in a large majority of those in which the spinal cord is involved, not so constant when the disease is confined to the brain.

The Colloidal Reactions. It has been found that the cerebro-spinal fluid in certain diseases contains substances (probably foreign proteins) which, when added to a colloidal suspension, cause precipitation. Lange, employing a suspension of gold chloride, first applied this knowledge as an aid to differential diagnosis, and the colloidal gold test now in general use bears his name. It has been found that whereas in normal fluids there is no precipitation, in syphilitic diseases of the brain or spinal cord some degree of precipitation is almost constant. The test is performed by adding 0.1 c.c. of spinal fluid to 0.9 c.c. of normal saline, and from this preparing successive dilutions of 1 in 20, 1 in 40, and so on, to weaker dilutions in a series of twelve tubes. To each of these 2.5 c.c. of colloidal gold are added. The results of the test are expressed either in a graph or numerically, complete precipitation being taken as 5 and no precipitation as 0. In general paralysis of the insane (syphilitic encephalitis) the precipitation is maximal in the first tubes of the series, and a typical result will read 5555544321. This is known as the "paretic" reaction. In other forms of neuro-syphilis the tendency is towards maximal precipitation in the middle zone of the series, as 3455443210. This type of result is known as the "luetie." It has been found that an abnormal gold curve may also occur in many cases of disseminated sclerosis. Here again it may be of some diagnostic value taken in conjunction

with the other tests. An abnormal curve, together with a positive Wassermann, spells syphilis. With a negative Wassermann it should in itself suggest disseminated sclerosis.

A cerebro-spinal fluid containing an excess of protein, from whatever cause, may give an abnormal colloidal curve.

DISEASES OF THE NERVES

Lesions of the cranial and peripheral nerves differ in certain respects from those of the central nervous system, and especially in regard to the degree of recovery which may occur after a lesion which is anatomically and physiologically complete. This, no doubt, depends upon the presence throughout the peripheral nervous system (including the cranial nerves) of the neurilemmal sheath which permits complete regeneration of the nerve, even after transection, by downgrowth from the central end. The cranial and peripheral nerves also, being comparatively avascular structures, are more resistant to the effects of pressure as from chronic inflammation or new growth than the tissues of the brain and spinal cord.

Although the term *neuritis* properly implies inflammation, it is widely used in a clinical sense to describe the symptoms which result from all kinds of disease of the peripheral nerves and nerve roots, including such diverse causes as infection, intoxication and trauma.

Of these *trauma*—whether from a single severe blow, from repeated minor injuries or from stretching—will produce a local effect involving damage to the nerve sheath and more or less damage to the nerve fibres. Local injury to a nerve fibre which stops short of destruction results in temporary disturbance or loss of function with rapid recovery. Local destruction, on the other hand, leads inevitably to secondary descending degeneration followed by the downgrowth of new fibres from above—a process which must occupy a considerable period of time, varying with the length to be traversed by the new fibres from site of injury to periphery.

New growths of other parts frequently compress, and sometimes infiltrate, nerves in their vicinity, and there are in addition certain tumours which may arise from the nerves themselves. Of these the commonest and most important is the neurofibroma, which may grow from the sheath of cranial or peripheral nerves, the auditory nerve being a favourite site. Often these tumours are multiple and are associated with von Recklinghausen's disease (*see* p. 980). Plexiform neuromas are of the same pathological type as the neurofibromas, but are softer and more diffuse. They are commonly confined to a single area of the body, where they form a nodular mass of interlacing cords. The malignant tumours arising from nerve sheaths are, as a rule, sarcomas, spindle or round-celled.

Local infection of a nerve may occur as the result of direct spread from inflammation in neighbouring structures—bone, muscle, fascia, etc.

In such instances of local damage the nerve is affected in its whole thickness, and, since the connective tissue elements comprising the nerve sheath bear the brunt of the injury, the process is sometimes called an *interstitial* neuritis to distinguish it from cases in which the neuro-fibrils themselves are directly injured by a selective poison. This latter variety is sometimes called *parenchymatous* neuritis.

Bacterial or chemical poisons which have a selective incidence upon the nerves, are, as a rule, conveyed thither by the blood stream. Their action, therefore, is as a rule symmetrical, often multiple.

In certain cases, however, bacterial poisons emanating from an infective focus may travel up the perineural lymphatic sheaths, and gain entrance to the neural elements at the point where the posterior nerve root enters the spinal cord. The work of Orr and Rows in this connection has already been mentioned, as

also the evidence for supposing that the initial neuritis of diphtheria is due to a lymphogenous intoxication of this kind. Occasionally one meets with other examples such as an ulnar or median neuritis developing after a septic finger.

Damage to nerve fibres, whether due to injury or disease, causes disturbance of sensation, muscular power and bulk, and vasomotor control. The injury to the lower motor neuron results in wasting, weakness and flabbiness of the muscles supplied. The tendon jerks of the affected muscles are diminished or lost owing to the loss of tone, and damage to the reflex arcs concerned. The disturbance of sensation takes the form at first of uncomfortable tingling (pins and needles) in the sensory distribution of the nerve, followed by anæsthesia. There may also in the early stages be cramp-like pains in the muscles. The trophic and vasomotor changes have already been referred to. In addition to these symptoms in the distribution of the nerve, there are in cases of local damage, pain, tenderness and sometimes swelling at the site of the disease. In severe lesions of motor nerves the electrical reactions are altered (*see p. 627*).

In recovery from injury to a nerve, or after reunion of a divided nerve signs of returning function should appear within three months. With the return of sensibility pin prick and extreme degrees of heat and cold are appreciated before cotton wool touches. The return of power in the paralysed part generally precedes any decided improvement in the electrical reactions. In severe lesions with extensive atrophy of muscle, R.D. persists for some time, but after some weeks the irritability of the muscle to galvanism also diminishes, and finally becomes extinct.

OLFACTORY NERVE

A diminution or loss of the sense of smell (*anosmia*) arises from altered conditions of the nasal mucous membrane, such as excessive dryness, or coryza, and in affections of the base of the skull involving the olfactory bulbs, such as injury, tumours, caries of the bone, and meningitis. It sometimes occurs in *tabes dorsalis*, and is not uncommon in hysteria, as a part of hysterical hemianæsthesia. It should be remembered that loss of smell may affect the power of appreciating flavours, which really requires the combined action of the sense of taste and the sense of smell through the posterior nares.

Morbid subjective sensations of smell occur in the insane, and sometimes as an aura in epilepsy.

The primary cause of these defects must be treated, if possible.

OPTIC NERVE

The main points of anatomical importance in connection with this nerve and the methods of investigating its functions have already been referred to (pp. 612 and 621, Fig. 71).

Affections of the Optic Nerve. With the ophthalmoscope it is not always possible to distinguish between *optic neuritis* and *papillœdema*, but it should be borne in mind that, despite their similarity, these two conditions are the result of quite different pathological processes (*see Plate 50*).

Papillœdema is the term used to denote swelling of the nerve head (or papilla) due to the mechanical conditions produced by increased intracranial pressure, from whatever cause. The increased pressure, being transmitted to the sheaths of the optic nerves by way of the cerebro-spinal fluid in the subarachnoid space, gives rise to compression of the veins, with resulting transudation through the vessel walls at the point of least resistance, which is the nerve head; the same factors cause a blockage of the paths whereby this transudate might naturally be absorbed, so that the condition is a progressive one, and the papillœdema may increase until the highest point on the nerve head stands out 2 or 3 mm. in front of the general retina.

Optic neuritis, as the term implies, is an inflammatory condition of the nerve which may be caused by various infective or toxic agents. It is a comparatively uncommon condition. It may or may not involve the nerve head. If it does so, the appearance on ophthalmoscopic examination resembles that seen in papilloedema, and it should strictly be called *papillitis*. If it does not, the condition is spoken of as a *retrobulbar neuritis*, and at first gives rise to no changes recognisable with the ophthalmoscope, though later on the disc may show the pallor of optic atrophy from spreading degeneration of the nerve fibres and their replacement by fibrous tissue.

The causes of *papilloedema* are those which give rise to increased intracranial tension, of which cerebral tumour is the commonest. The causes of *papillitis* are few. It may be encountered in renal disease, in disseminated sclerosis when a patch of the disease happens to involve the nerve head, and rarely in other infective or toxic conditions. The common cause of *retrobulbar neuritis* is disseminated sclerosis. Methyl alcohol poisoning, or combined poisoning with ethyl alcohol and nicotine are occasional causes.

Optic Atrophy. This may be produced as the result of various processes, of which the most important are:—

1. Degeneration of the nerve fibres as the result of *syphilitic infection*; the disc is of a greyish pallor with clear-cut edges; this is frequently seen in *tabes* and *dementia paralytica*.

2. Degeneration of the nerve fibres secondary to a *retrobulbar neuritis*; this is most commonly seen in disseminated sclerosis, in which the disc shows a dead-white pallor, which is best marked on the temporal side.

3. Degeneration of the nerve fibres as the result of *pressure* upon the optic nerve or optic tract. In this case the disc presents an appearance of startling pallor with exceedingly clear-cut edges.

4. Degeneration of nerve fibres *secondary to papilloedema* or *papillitis* with organisation of the exudate. The nerve head is dead white, but may still show some swelling; the edges are indistinct, the physiological cup is filled in, and there are whitish streaks of exudate along the course of the vessels.

Optic atrophy of the first three types mentioned above is often called *primary optic atrophy*, in order to distinguish it from the *secondary optic atrophy* following swelling of the disc from œdema or inflammation. Vision is very greatly reduced or abolished in optic atrophy.

THIRD, FOURTH, AND SIXTH NERVES

The lesions causing ocular paralysis may affect—

1. The trunks of the nerves. Here the lesions are syphilitic and so-called rheumatic inflammations and toxic neuritis; the pressure of orbital or intracranial growths, or of aneurysms, and rarely tumours of the nerves themselves; direct injury; and inflammation or suppuration spreading from the middle ear.

2. The nerve fibres in the brain connecting the nerve trunks with the nuclei, the chief causes being hæmorrhage, softening, tumours, and disseminated sclerosis.

3. The nerve nuclei. Nuclear palsies may be caused by focal lesions of the same type as those just mentioned, or they may be due to the selective action of some poison upon the nuclei themselves, as in *tabes*. A focal lesion can usually be distinguished from primary nuclear disease by the implication in the former of neighbouring structures, leading to nystagmus or the signs of motor and sensory disturbance. In the case of the fourth and sixth nerves it may be impossible to distinguish between a lesion of the nucleus and the nerve trunk. The third nerve, however, supplies the pupil, the upper lid and several of the muscles which rotate the eyeball. In a lesion of its trunk all these functions are affected together, whereas a nuclear lesion is apt to affect them separately. A lesion, for instance, in the anterior part of the nucleus may result in ptosis, pupillary paralysis and failure of

upward movement of the eyeballs, without any affection of the other muscles. Apart from disease of the oculomotor nerves myasthenia gravis should be remembered as a not uncommon cause of ocular palsy.

Treatment of Ocular Paralysis. This must depend upon the cause, if it can be ascertained. Syphilitic cases—and they form a very large proportion—should be treated by salvarsan and potassium iodide and mercury. For cases of an inflammatory nature counter-irritation by a blister behind the ear or leeches to the temple should be tried. If the paralysis has appeared to follow after exposure to cold, hot fomentations should be applied, and salicylates may be given internally. The so-called rheumatic cases, however, tend to recover without treatment. Diplopia may be relieved by the use of a prism, which should not be strong enough to fuse the images, but only to approximate them, so that muscular efforts may be encouraged.

FIFTH NERVE

The fifth nerve may be injured in any part of its course. In the pons its origin may suffer from tumours or hæmorrhage; its trunk may be affected by tumours or meningitis at the base of the brain; in front of the Gasserian ganglion the first division is liable to pressure from aneurysm, tumour or meningitis; the second and third divisions may be injured by growths arising in the nose or pharynx. Injuries to the mouth or nose may involve various branches of the second and third divisions, and neuritis of these branches may be caused by neighbouring inflammations.

Symptoms. These must depend on the position of the lesion. If the *sensory* fibres are involved, the result is anæsthesia of the face, corresponding to the distribution of the nerve. The loss of sensation is often preceded by tingling and numbness or neuralgic pains. The conjunctiva and the nasal and buccal mucous membrane are, of course, involved as well as the skin. If the sensory root of the ganglion or its ophthalmic division be involved the corneal reflex is lost early, and, when corneal anæsthesia is complete, as the result of unheeded irritation from foreign bodies, inflammation (neuro-paralytic keratitis) often occurs and the eye may eventually be destroyed. When the third division is involved, in consequence of the mouth being insensitive on one side, food is not chewed on that side, and a thick fur collects on the tongue for want of the cleaning operation of mastication.

Herpes zoster occurs especially in connection with the first division (*Herpes zoster ophthalmicus*), and appears to arise from inflammation of the Gasserian ganglion.

If the *motor* portion of the fifth nerve is involved, which is only likely to happen in lesions near the origin of the nerve, the temporal, masseter, and pterygoid muscles are paralysed, and after a time atrophy of the temporal and masseter muscles may be recognised.

Lesions of the sensory root between the ganglion and the pons usually give rise to progressive numbness and anæsthesia without pain. In the case of lesions of the ganglion itself or its branches anæsthesia is preceded or accompanied by pain. Paroxysmal trigeminal neuralgia is described on p. 754.

Diagnosis. The presence of severe pain may give for a time a resemblance to neuralgia, but anæsthesia, diminution or loss of corneal reflex, or wasting of the muscles supplied by the motor root prove an organic origin. If one or other branch is alone affected the lesion is in front of the Gasserian ganglion; if all the branches, it must be near the origin. The association of other nerve paralyses, such as those of the ocular nerves, or of the motor tract, may also help to localise the lesion.

Treatment. Besides dealing with the cause where this is possible, relief from pain may be obtained by injection with alcohol of the Gasserian ganglion or its branches.

SEVENTH OR FACIAL NERVE

The pathological interest of the seventh nerve chiefly centres in its motor fibres, and its tortuous course from the pons through a bony canal to its distribution on the face renders it especially liable to inflammation and compression. A focal lesion affecting the seventh nucleus almost inevitably produces other symptoms from involvement of the neighbouring structures, especially the sixth nerve. In its course through the cerebello-pontine angle the seventh nerve is closely associated with the fifth, sixth and eighth nerves, so that one or more of these are usually involved with it by disease in this situation. In the first part of its bony canal it is in close contact with the eighth nerve. An isolated affection of the seventh nerve is therefore most commonly due to a lesion in the lower part of the facial canal, or after its emergence from the stylo-mastoid foramen.

Nuclear palsies may be caused by inflammation or growth. In its intracranial course the nerve is not infrequently affected by a tumour in the cerebello-pontine angle, or by syphilitic meningitis. In the upper part of its bony course it is commonly involved by an extension of middle ear disease in this direction.

The commonest variety of facial paralysis, however, is that in which this nerve is affected alone by what is presumably an infective or toxic neuritis. The condition is known as Bell's palsy.

Bell's Palsy. This may occur at any age and affects both sexes equally. The ætiology is unknown, but exposure to cold seems to play a part in the causation of some cases. The onset is usually acute, and may be preceded by complaint of pains about the site of the stylo-mastoid foramen. The patient finds himself conscious of loss of power in the facial muscles and often complains that his face is drawn up towards the opposite side. Mastication and articulation are interfered with, and the eye becomes sore owing to incomplete closure of the lids.

Within twenty-four hours of the onset the progressive stage of the affection is at an end. It is then possible to estimate the degree of paralysis. In a moderately severe case all the facial muscles will be found paralysed with the exception of orbicularis palpebrarum, in which power is seldom completely lost. After a variable interval power gradually returns, beginning with orbicularis palpebrarum, and in the majority of cases recovery is complete within two months from the onset.

In estimating the prognosis the electrical reactions are of great value. A fortnight should be allowed to elapse before these are tested. If at this date from the onset the facial muscles respond to faradism the prognosis is good. Cases showing R.D. are unlikely to make a complete recovery.

A partial recovery is often followed by contracture of the paralysed muscles. These are somewhat shortened, the eye is a little closed, and the angle of the mouth is slightly drawn up by the zygomatici; and if the muscles of the sound side are at rest, the first impression that one gets is that the paralysed side is active and that the sound side is paralysed. This idea is corrected at once when the patient speaks or smiles, or tries to shut the eyes. The contracted side can contract very little more, while the sound side has a wide range of movement. In this condition also the affected muscles cannot be moved independently—in closing the eye, the angle of the mouth is raised; in smiling, the eye is partially closed. This is called *secondary over-action*. In children facial paralysis is not so obvious as in adults, because elastic tissue plays a greater part in the facial expression of children, whereas in older people the muscles are all important.

Diagnosis. The recognition of facial paralysis is not difficult. Bell's palsy is by far the most common variety, and may be distinguished by its sudden onset and the absence of other signs. The presence of middle ear disease on the affected side should always be looked for. Facial weakness from an upper neuron lesion may, as a rule, be distinguished easily owing to the fact that in this

the lower facial muscles are much more affected than the upper, and there is usually an associated weakness of palate and tongue. The electrical reactions also are normal.

Prognosis. This will vary with the cause. The prognosis in Bell's palsy has already been discussed above.

Treatment. Apart from treatment of the cause, where this can be found, attention should be directed towards preserving the functions of the weakened muscles. Electrical treatment may usefully be employed so long as the muscles cannot be exercised by the will. When the muscles respond to faradism electrical treatment can easily be managed. If they do not the galvanic current must be employed. The patient should also be encouraged to practise the use of his facial muscles daily before a mirror. Massage may also be of value. In a severe case the flaccid muscles on the paralysed side may be supported in the position of rest by means of a piece of copper wire ensheathed in rubber tubing, the two ends being bent so that one fits over the ear and the other hooks into the angle of the mouth.

EIGHTH NERVE

Various cerebral lesions may involve the nuclei of the nerve in the pons, or its higher connections in the brain; the nerve itself may be injured by meningitis, aneurysms or tumours; and the expansion of the nerve in the labyrinth may be damaged by acute or chronic inflammation, by syphilitic disease, or degenerative changes.

The results of these lesions are *deafness*, *vertigo*, and various subjective sounds, especially *tinnitus*.

Deafness from the above cause is called "nerve" deafness, and has to be distinguished from loss of hearing due to interference with the conduction of sound through the middle ear and external auditory meatus (*see* p. 621).

When the conduction is found to be normal, deafness must be due to a lesion either of the nerve or of the labyrinth. Which of these is more likely to be at fault must be determined by associated symptoms. These may sometimes point to an intracranial lesion, but, as a fact, deafness is not a very common symptom in cerebral cases, unless the trunk of the auditory nerve is directly compressed by a tumour.

Tinnitus Aurium. This term includes the various subjective sensations of sound, generally of a hissing, whistling, ringing, or roaring kind, with which, in their slightest degrees, nearly every one is familiar. It is clearly due to irritation of the auditory nerve fibres, and may occur in almost any form of disease of the ear, whether of the external meatus, of the middle ear, of the labyrinth, or of the nerve or nerve centres. Thus it may result from cerumen in the external meatus, is not infrequently present in acute and chronic inflammations of the middle ear, and is a prominent symptom in cases of tumour involving the eighth nerve between the internal auditory meatus and the pons. The commonest cause of tinnitus, however, is disease of the nerve endings of the cochlear apparatus. These may be affected temporarily by the action of certain drugs, especially quinine and the salicylates, or as a result of defective blood supply, *e.g.* in the secondary anæmia following a severe hæmorrhage. More frequently the tinnitus is associated with progressive deafness and is due to irritation of the nerve fibres as a preliminary to destruction. The cause in such cases may be disease of the bony capsule of the cochlea (otosclerosis), degenerative changes in the arteries leading to a permanently defective blood supply, or primary degenerative changes in the nerve fibres themselves as in the common form of Ménière's syndrome, whose cause is unknown, and which is sometimes called Ménière's disease. In the last instance the vestibular nerve endings are also affected with resultant attacks of vertigo.

Treatment. The cause of the tinnitus must be first considered. Disease of

the external or middle ear should be directly treated. In the cases of obscure origin the symptom may be alleviated by the avoidance of fatigue, especially of the mental order, and the prescription of sedatives such as bromide and luminal in small doses taken regularly.

Vertigo. The complaint of giddiness is a common one, and it is of the greatest importance in diagnosis that one should ascertain what are the actual sensations of the patient who uses this word to cover them. Disease or disorder of the vestibular nerve endings or their central connections gives rise to characteristic symptoms for which the term vertigo should be reserved. These may take the form either of sudden and transitory attacks or of a more continuous sensation. In the former instance the patient has a false sensation of movement of surrounding objects, of himself, or of both. The movement may be in any direction and is often rotary. Thus surrounding objects may appear to revolve in a clockwise or counter-clockwise direction, the ground may seem to come up towards the patient's eyes, or the ceiling fall; or again he may appear to himself to be spinning or falling in one direction or another. In a severe attack he may fall. The after effects of such an attack may last for minutes, hours, or days, depending upon its severity, and during this period the patient has sensations of vertigo on movement, especially any quick movement of the head. At the height of the attack vomiting is a common symptom and may be severe and prolonged.

Vertiginous sensations of the milder degree may occur without any initial attack, the patient complaining of a continued state of unsteadiness which is aggravated by movement of the eyes or head.

Vertigo may be caused by an inequality of pressure upon the two sides of the tympanic membrane as from a plug of wax in the meatus, or a blocked Eustachian tube; by acute or chronic otitis media; by chronic degenerative disease affecting the middle and internal ear; by syphilitic and arterial disease of the latter; by tumour or syphilis involving the eighth nerve; and by vascular lesions, syphilis, tumour or disseminated sclerosis affecting the central connections of the vestibular nerve in the brain-stem and cerebellum. Vertigo may also occur as the aura of an epileptic attack from disease of the cerebral cortex.

The first question to be asked when vertigo is encountered is whether it is associated with deafness or tinnitus, if so the lesion is almost certainly in the middle or internal ear or the eighth nerve. Affections of the latter are usually associated with involvement of other cranial nerves, especially the fifth, sixth and seventh. By a process of exclusion, therefore, the situation of disease in the ear can be inferred when present.

Lesions of the brain-stem or cerebellum are not necessarily associated with deafness or tinnitus, but give rise to other symptoms and signs (inco-ordination, paralysis, anæsthesia) which are of localising value. Vertigo as an epileptic aura is followed by disturbance or loss of consciousness. The aura may occur without any subsequent attack, but it is brief and is not followed by any after-math in the shape of vertiginous sensations.

In the great majority of cases vertigo is due to that form of degeneration affecting the internal ear whose cause is unknown and which is sometimes called Ménière's disease.

Treatment. Vertigo is to be regarded as a symptom rather than a disease, and treatment must, therefore, be directed to the underlying cause when this has been ascertained. In cases due to chronic otitis media surgical treatment is required. In some instances syphilis is the cause of a destructive labyrinthitis and should be treated by the appropriate remedies. In those cases in which the pathology is obscure, potassium bromide appears to be of value in diminishing the frequency and the severity of the attacks, and should be given in doses of from 15 to 20 grains three times a day. Luminal, in doses of $\frac{1}{2}$ grain thrice daily, or 1 grain night and morning, is perhaps even more valuable. When the

cause of the vertigo can be localised with certainty to the labyrinth and the disease is unilateral, relief may be offered by means of operation. Either the labyrinth is exposed and destroyed by injection of alcohol, or the eighth nerve is cut within the skull. Such procedures should be reserved for patients whose attacks are severe and disabling, but are then well worth consideration in that they afford the only means of permanent relief.

Ménière's Syndrome and Ménière's Disease. It has already been pointed out that the commonest cause of both tinnitus and vertigo is disease of the labyrinth from whatever cause, these two symptoms being then associated with deafness. This triad of symptoms is known as Ménière's syndrome, after the French physician who first described it and correctly inferred its labyrinthine origin. In one of the first cases which Ménière observed the symptoms came on acutely. The patient died, and the appearances suggested a hæmorrhage into the labyrinth. In all probability this was a case of acute streptococcal infection. Such cases are extremely rare. Commoner causes of labyrinthine disease are chronic otitis media, arteriosclerosis, head injury, and syphilis. It must be remembered also that Ménière's syndrome may be reproduced by disease affecting the eighth nerve, in particular the so called acoustic neurofibroma.

But in the great majority of patients who present Ménière's syndrome none of these causes are to be found. The story is usually that of a gradual onset of tinnitus and deafness, which begins in one ear, and after a considerable interval, usually of years, affects the other, the whole period being punctuated by attacks of vertigo. There may be long remissions in the course of the disease, and the state of the hearing may vary from time to time. Nerve deafness is always present but may be associated with middle ear deafness. For this large group of cases of uncertain cause Mygind and Dederding propose the term Ménière's disease, defining this as "a disease which so far as the ear is concerned shows itself by a varying function both of the acoustic and the static part, and with regard to which it has been possible to exclude any specific ætiology." Ménière's disease in this sense is a term which may be used with advantage provided that its implication of an undiscovered cause is remembered. The writer has observed in a series of patients with Ménière's disease that 9 per cent. also suffered from typical attacks of migraine (see p. 747).

NINTH OR GLOSSO-PHARYNGEAL NERVE

The nerve is rarely affected alone, but may be involved in tumours at the base of the skull together with the other nerves which pass through the jugular foramen. Its destruction results in anæsthesia of the mucous membrane covering the tonsillar region, and the posterior part of the tongue and soft palate on the affected side. The glosso-pharyngeal nerve may also be the seat of paroxysmal neuralgia, the pain being referred to the parts just mentioned and to the region of the ear drum and Eustachian tube. It is excited by movement of the fauces or tongue or contact of food with these parts, occurs in bouts of progressive frequency and severity, and is relieved only by section of the nerve.

TENTH, OR VAGUS NERVE

The motor nuclei of the vagus besides being responsible for the innervation of a considerable extent of the smooth muscle of the thoracic and abdominal viscera, supply motor fibres to the voluntary muscles of palate, pharynx and larynx. The sensory nucleus is concerned with visceral sensation only. The vagal nuclei in the medulla may be affected by thrombosis, hæmorrhage, new growth, syringomyelia, poliomyelitis or degenerative change (progressive bulbar palsy). At the base of the skull the nerve may be compressed by new growth or chronic inflammation (syphilitic, tuberculous or suppurative) of meninges or skull. In

the neck and chest the trunk of the nerve or its recurrent laryngeal branch are not infrequently involved by aneurysm, new growth or enlarged glands.

The symptoms to be looked for in a lesion of the vagus are those which result from paralysis of palate, pharynx and vocal cord.

The *palate* on the affected side fails to rise on phonation, the uvula being drawn over to the unaffected side. The posterior wall of the *pharynx* on the affected side is drawn laterally over to the unaffected side on phonation (curtain movement of pharynx).

The *vocal cord*, following a lesion at any point between the nucleus and the recurrent laryngeal nerve, is completely paralysed and lies in the cadaveric position. With this there is usually some hoarseness and difficulty in coughing. A lesion of the recurrent laryngeal nerve results in abductor paralysis only, and phonation and coughing are unaffected. The vomiting, irregular respiration and slow pulse rate, which occur as the result of increased intracranial pressure, are presumably due to the effects of the pressure upon the vagal nuclei. (*See also* p. 208.)

Treatment must be conducted on the lines indicated in the case of other nerves. (*See also* Diseases of the Larynx.)

ELEVENTH OR SPINAL ACCESSORY NERVE

The external portion of this nerve arises by a series of roots from the cervical part of the spinal cord, and is really a motor spinal nerve directly connected with the anterior cornua. It is distributed to the sterno-mastoid and trapezius muscles.

In addition to cerebral and intracranial lesions, like those which may involve the vagus, the spinal accessory may be injured by caries of the cervical spine, by enlarged glands or abscesses in the neck, or by blows and strains. If the lesion is in the posterior triangle, the sterno-mastoid will of course be spared. Paralysis of the sterno-mastoid is shown by the want of prominence due to contraction of this muscle, and by deficient power of rotation of the head to the opposite side. In paralysis of the trapezius, the natural slope between the neck and the shoulder is converted into a deep hollow, which is exaggerated when the shoulder is raised, as it still can be by the action of the levator anguli scapulæ. The point of the shoulder lies lower than normal, and the posterior border of the scapula is inclined from below upwards and outwards. Elevation of the hand above the head is, however, difficult or impossible, because the trapezius does not fix the scapula for the use of the deltoid, nor does it assist in that rotation for which the serratus magnus is chiefly employed. With a persisting lesion atrophy and electrical changes naturally follow.

Treatment. Here we must deal, when possible, with the causative lesion and with the muscular failure by electrical stimulation, and massage.

TWELFTH OR HYPOGLOSSAL NERVE

The commonest cause of a muscular lesion is motor neuron disease (progressive bulbar palsy), both nuclei being affected together. Unilateral destruction of the nerve fibres in their intramedullary course occurs in occlusion of the postero-inferior cerebellar artery. At the base of the brain the nerve may be involved by new growth or syphilitic meningitis, and outside the skull by malignant glands, inflammation or injury. When one side of the tongue is paralysed the organ is pushed over to the affected side on protrusion. When the paralysis is bilateral the tongue lies motionless in the mouth and deglutition and articulation are seriously affected. Wasting of the muscles results in a wrinkled appearance of the mucous membrane, which is especially apparent when the affection is unilateral. Fibrillation is usually to be seen in the wasting muscles. This again is easily

recognised when the paralysis is unilateral, but in the case of bilateral palsy may be confused with the fine irregular tremor often seen in the protruded tongue of a normal person. In such cases it is best looked for with the tongue lying at rest in the open mouth.

Treatment. This must follow the causal indications.

LESIONS OF SPINAL AND PERIPHERAL NERVES

The spinal nerves may be injured or diseased at the roots, or in the plexus or nerve trunks beyond them.

Lesions of the nerve roots arise in connection with diseases, injuries and tumours of the spinal cord or spinal column, and the symptoms may be combined with those of the central affection, as, for instance, in the case of a tumour growing from the dura mater, syphilitic meningitis or tuberculous caries. Lesions of the spinal nerve trunks are mostly from new growths, aneurysms, and abscesses in or near the spinal column. The roots emerging from the intervertebral foramina may also be affected in the course of a rheumatic fibrositis (radiculitis). Effusion into the nerve sheaths may also occur as the result of comparatively slight trauma, or excessive stretching, especially if this is often repeated. Inflammation of the nerve sheaths sometimes results from poisons gaining access from the blood stream, and these may be either of bacterial origin or by-products of faulty metabolism. Owing probably to their more exposed position and greater liability to stretching the nerve fibres of the brachial and sciatic plexuses are those chiefly affected by these causes.

Since the spinal nerves contain both motor and sensory fibres, the symptoms of their lesions are both loss of muscular power and anæsthesia, determined by the distribution of the nerve fibres to muscles and skin respectively. If the lesion is persistent, atrophy and altered electrical reactions (*see* p. 627) of the muscles will ensue, and perhaps trophic changes in the skin.

Treatment. The results of these lesions which require treatment are paralysis and muscular atrophy on the one hand, and pain or other sensory symptoms on the other. In either case a removable cause, such as pressure by abscess or tumour, should, if possible, be dealt with; or, if a toxic neuritis is the presumed cause, all possible sources of infection or intoxication in the body should be investigated and remedied as far as may be, *e.g.* pyorrhœa alveolaris, septic tonsils, chronic infections of the alimentary tract. Atophan and aspirin may be given internally, and dietetic reform prescribed in cases suspected of a gouty origin. Massage, electrical stimulation and exercises are of use in dealing with the paralysis. For pain the local application of heat, or of the liniments of belladonna, aconite, turpentine, etc., may be valuable. *Rest* is also essential for a quick recovery; the arm should be carried in a sling, or, if the leg is affected, the patient should lie in bed, and when necessary special splints should be employed to maintain paralysed muscles in the position of rest.

Some of the more important and frequent lesions of the spinal nerves are here shortly described.

UPPER CERVICAL NERVES

These may be involved in diseases of the upper part of the spine, especially in tuberculous disease of the atlas or axis. The posterior rami are often affected by neuritis of traumatic or toxic origin. The common "crick" of the neck is a familiar example of minor injury, and in persons predisposed to toxic neuritis cold appears to be a deciding factor in producing an attack (*e.g.* sitting in a draught). If the trouble is confined to the branches of the second cervical nerve the pain is felt in the occipital and sub-occipital regions and is frequently complained of as headache. Tenderness over the scalp and the points of emergence of the great occipital nerves are present during the paroxysms of pain and serve to distinguish these cases from those of intracranial disease.

use, *e.g.* hot water bottles or an electrically heated pad continuously applied to the painful spots.

As a counter-irritant a mustard leaf applied over the centre of pain with three or four layers of handkerchief between it and the skin is often valuable. Used thus it may be allowed to remain *in situ* for six or eight hours without raising a blister, and the application may be repeated as soon as the state of the skin will allow it. Diathermy and galvanism may also exert a sedative action.

As a rule the patient may be allowed to get out of bed to the lavatory or commode, but when, despite this degree of rest, after a few days the pain continues unabated, he should be nursed continuously in bed.

The motions should be kept soft by means of liquid paraffin.

Various accessory methods of treatment have been devised from time to time whose object is to stretch the nerve or its roots and so break down adhesions. These are best avoided in the acute stage, and will naturally be left alone at a later stage when progress is satisfactory. In some cases, however, a point is reached when the patient is free from pain except during or after certain movements, and it is in these that stretching may be of value. The methods in use are injection of saline into the nerve trunk below the sciatic notch, injection of saline under tension into the epidural space through the sacro-coccygeal foramen, or manipulation of the affected limb and lower back under general anæsthesia. In the writer's experience the last method has been the most successful, but it should be reserved for selected cases.

Most patients with sciatica will recover completely with rest, heat, sedatives and analgesics if they can be persuaded to persevere with this treatment. Rest should be strictly maintained until the patient has been reasonably free from pain for a few days before any liberty of movement is allowed, and it should then be remembered that movement of a kind which does not cause pain at the time may be followed by it afterwards. Great care, therefore, should be exercised in treading the path of convalescence. For some time stooping movements should be avoided and a cushion or rubber ring should be used to avoid pressure in sitting. In the final stage of convalescence massage and exercises are of use in restoring the function of the limb and correcting faulty posture.

The part played by focal sepsis in the causation of sciatica is doubtful. Infected teeth or tonsils are generally best left alone during the attack, but may be dealt with later with the object of preventing recurrence, and with the same end in view modifications of diet and *régime* may be advised.

Meralgia Paræsthetica. This is an affection, probably inflammatory, of the external cutaneous nerve of the lumbar plexus. The symptoms are *pain*, sometimes brought on by walking, at others when the patient is lying still or sitting, and abnormal sensations, such as numbness, pins and needles, cold feeling, burning sensation of tightness, felt on the front and outer part of the thigh within the distribution of the above nerve. Over the same area there is some modification of sensibility, either hyperæsthesia, or more often anæsthesia, or changes in the appreciation of pain, heat or cold. In most cases there is some tenderness on pressure below the anterior superior iliac spine, where the nerve comes through the fascia lata. It is more frequent in men than in women, and has been attributed in different cases to injury and to toxic and infective agents. Rest, warm baths, and counter-irritants should be tried for its treatment.

In chronic cases the nerve may be found constricted by fibrous contracture of the opening in the fascia lata, and the condition may be relieved by the minor operation of slitting up the channel in the fascia and so releasing the nerve from pressure.

MULTIPLE NEURITIS

(*Peripheral Neuritis, Polyneuritis*)

Ætiology. It is in only a minority of cases that the cause can be definitely traced. The known causes may be divided into: (1) Poisons introduced into

the body from without. Of these the best known are alcohol and arsenic. Carbon bisulphide, carbon monoxide and dinitro-benzol may also be responsible. Lead is often included in this category, but acts rather upon the muscle fibre directly and the anterior horn cells (p. 588). (2) Poisons arising within the body. Of these the commonest is hyperglycæmia in diabetes. Beri-beri may also be included in this class, as also certain rare instances in which polyneuritis and hæmatoporphyrinuria are associated. Probably a number of the cases of obscure origin are caused by toxins arising in the body as the result of faulty metabolism, and these are sometimes spoken of as "gouty" or "rheumatic." (3) Bacterial toxins. The common instance is diphtheria, but polyneuritis has been recorded as a rare complication of many other infective fevers. (4) There appears to be a special liability in cachectic states such as accompany malignant disease and tuberculosis.

Morbid Anatomy. The characteristic picture is of degenerative changes in the nerve fibres, without affection of the nerve sheaths. There is thus no abnormality visible to the naked eye, but microscopic examination by the Marchi method shows fragmentation and fatty degeneration of the myelin sheath. The axis cylinders are less affected. These degenerative changes are most marked in the peripheral nerve twigs, being slighter as one approaches the spinal cord, and the anterior roots are usually normal.

Symptoms. The clinical picture of polyneuritis varies somewhat with the cause in operation. The following description applies to the majority of cases.

The onset, as a rule, is gradual, with complaint of "tingling," or "pins and needles" in the toes and fingers. These subjective sensations of discomfort gradually spread upwards, but do not usually advance higher than the knees and wrists. They are commonly accompanied by occasional "cramps" of a painful nature in the muscles of leg and forearm. Motor symptoms as a rule follow the sensory disturbance. There is weakness, especially of the dorsiflexors of the feet with consequent foot-drop, and in walking the knees are lifted high in order that the hanging toes may clear the ground ("steppage gait"). The movements of the fingers are impaired so that the grip is weakened and fine movements, such as doing up buttons, become impossible. If the weakness extends higher in the arms the extensors of the wrists are usually next affected with the appearance of "wrist drop." The circulation in the affected extremities is often enfeebled so that they become cold and blue.

On examination it is found that cutaneous sensibility is impaired in the areas in which numbness and tingling are complained of, the degree of impairment being less as one proceeds upwards from the periphery. Deep sensibility is less affected, and the muscles are frequently unusually tender to pressure. The enfeebled muscles are flabby, and if the disease has been present for more than two or three weeks, show wasting, which is most evident in the small muscles of feet and hands, and the calves of the legs. The tendon jerks in the earliest phase of the disease are temporarily exalted. Later they are diminished or lost, the earliest to disappear as a rule being the ankle jerks; loss of knee jerks follows if the case is a severe one, and the supinator jerks also are affected if the upper limbs are extensively involved.

The symptoms are usually symmetrical, but may commence in one extremity before the others. The lower limbs are, as a rule, more severely affected than the upper.

The cranial nerves are not affected, and there is no loss of sphincter control.

In some cases, however, although the initial complaints are very much the same the clinical picture develops in a different form. Deep sensibility—including sense of position and passive movement, and the vibration sense—is extensively affected, and muscular weakness is more widely and more evenly distributed. The patient then has difficulty in estimating the extent and direction of his movements, and therefore staggers in his gait, flinging his lower limbs about in a

manner reminiscent of tabes. This clinical variety is known as *ataxic polyneuritis*, and is probably due to an extension of the toxic effect to the posterior columns of the spinal cord.

Polyneuritis is sometimes accompanied by a peculiar condition of mind, which is most frequent in alcoholic neuritis, but also occurs, as was first observed by Korsakow, in multiple neuritis from other toxic causes (puerperal septicæmia, typhoid, influenza). He therefore called it *psychosis polyneuritica*, and it is also known as *Korsakow's syndrome*. The patient suffers from loss of memory for recent events, is ignorant of his whereabouts, has false memory, and describes events which have never happened. Thus he will be unable to tell his name, age, the day of the week, or where he comes from; but, on the other hand, he may say that he has been for a walk, a ride, or has seen certain friends, in obvious antagonism to facts. There may be a stage of talkativeness, or even delirium; but in advanced cases the patients show extreme apathy, and complete indifference to surroundings.

In cases of known causation there occur variations from this description, which in some instances are characteristic. Those in the case of diphtheria and lead-poisoning are described on pp. 65, 588.

Alcoholic Neuritis occurs more often in women than in men, and commonly results from frequent slight excess. It is at present a rare disease in this country. Other signs of chronic alcoholism, such as dyspepsia and cirrhosis of the liver, may or may not be present. The lower limbs are more seriously affected than the upper and may be involved alone.

Complaint of painful cramp in the calves and tenderness of the same parts to pressure are prominent symptoms. Of the cranial nerves the vagus is sometimes affected, leading to persistent tachycardia, and (rarely) to laryngeal paralysis. Nystagmoid jerkings of the eyeballs are often present (due probably to slight weakness of the motor nerves), and the facial muscles may also be involved.

Arsenical Neuritis. This occurs occasionally as a result of continued full doses of arsenical preparations given medicinally. In the year 1900, in Manchester and some other towns in the north of England, a number of cases of neuritis, at first thought to be due to alcohol, were shown to be caused by the accidental impregnation of beer with arsenic in the process of brewing.

The distribution and character of the sensory and motor symptoms are much the same as in alcoholic neuritis, but there are in the arsenical form greater cutaneous hyperæsthesia, more frequent affection of the facial muscles and lower intercostal muscles, earlier atrophy, more frequent inco-ordination, and more rapid progress (Judson Bury), and extreme sensitiveness of the muscles to pressure (Reynolds).

Diabetic Neuritis. Although the complete clinical picture of polyneuritis may be met with in this disease, more commonly it is found that the ankle and knee jerks are diminished or absent without any sensory complaint or localised muscular weakness; in the latter case degeneration of the posterior columns has been found as in tabes.

Acute Febrile (or Toxic) Polyneuritis. This is a somewhat rare illness, in which preliminary symptoms of constitutional disturbance with or without pyrexia are rapidly followed by those of polyneuritis, without any discoverable cause. The cranial nerves are frequently involved, especially the seventh, and if, as often occurs, this affection is bilateral, a remarkably expressionless facies results. Superficial sensibility is little affected, nor is pain at all a prominent feature, but there may be considerable loss of the senses of position and passive movement. The weakness is more widespread and more evenly distributed than in most cases of polyneuritis caused by known poisons. In some cases the proximal rather than the peripheral groups of muscles may be involved. There is some risk to life from broncho-pneumonia in the early stages, if the muscles of deglutition

are involved, but after two or three weeks steady improvement sets in, and complete recovery may be expected.

Associated Conditions. As neuritis is frequently caused by poisons from without, such as alcohol, arsenic, and lead, its symptoms are often associated with others due to the particular poison concerned: thus in alcoholic cases cirrhosis of the liver may be present; in arsenical cases, various lesions of the skin, viz. pigmentation, keratosis or hypertrophy of the epidermis, erythema and herpes zoster. Cardiac failure with œdema occurs with the neuritis of beri-beri, and may be present in arsenical, alcoholic, and diphtherial cases.

Diagnosis. The early symptoms of polyneuritis bear a close resemblance to those of *subacute combined degeneration*. The peripheral numbness and weakness and loss of ankle and knee jerks are common to both. In combined degeneration, however, symptoms of spinal cord disease are usually present in the form of girdle pains, sphincter disturbance, or extensor plantar responses. Lesions of the lumbar enlargement of the spinal cord or cauda equina may also produce weakness of the lower limbs with absent tendon jerks, but here again sphincter disturbance and the segmental distribution of the anæsthesia are points of distinction. Some cases, especially those of the ataxic form of polyneuritis, need to be distinguished from tabes. But in the latter disease there is usually a history of lightning pains, quite unlike the sensory complaints of neuritis, the arms are rarely affected at the same time as the legs, and the calf muscles, so far from being tender, are unusually insensitive to pressure. Other signs of tabes, especially Argyll-Robertson pupils, are also of use in the differential diagnosis.

Acute febrile polyneuritis in a child may easily be mistaken for poliomyelitis, but in the former disease the distribution of the weakness is more symmetrical, its degree more uniform and its development more gradual. The afebrile or toxic variety, especially if the onset is relatively gradual and sensory disturbance is slight, may need to be distinguished from motor neuron disease (progressive muscular atrophy).

A point which is sometimes of value in differential diagnosis is that in cases of polyneuritis, especially the acute or rapidly progressive forms, there is usually a considerable excess of protein in the cerebro-spinal fluid without any corresponding increase in the number of cells.

Prognosis. Alcoholic cases may be fatal either in an early stage where the cause is not promptly removed, or after months from emaciation, or bedsores, or phthisis. In many cases the symptoms develop rapidly in the first six or eight weeks, and then the condition of the patient may remain stationary for months, or very slowly improve. After years recovery may be only partial. But in alcoholic and in other cases where the disease is not too far advanced, and the cause can be completely removed, the prognosis is more favourable, recovery taking place slowly in the course of from two to six months. In the cases of unknown origin complete recovery is the general rule, although relapses may occur. The duration of the illness varies with its severity. When the paralysis is widespread and severe it may be a year or more before recovery is complete.

Treatment. If any external poison such as alcohol or arsenic is the cause, it must be henceforth kept from the patient. In diabetic cases the cause should be treated. In acute and severe cases complete rest is sometimes necessary, at first on account of the muscular pains. As soon as possible massage and active and passive movements should be commenced: in milder cases these measures should be employed from the beginning. In very slight cases it is not necessary that the patient should go to bed, but he should be warned against fatiguing the affected limbs. Splints are frequently necessary to prevent contractions. In severe cases these must be worn continuously. At a later stage of the illness, or in less severe cases, it will suffice that they should be worn at night only. The

electric current should be used to stimulate muscles which cannot be exercised by the will.

Of drugs, aspirin is useful for the pains of onset : atophan may be given in cases suspected to be of gouty causation : and a strychnine mixture should be prescribed during convalescence. (*See also treatment of fibrositis.*)

LOCALISED MUSCULAR SPASM

Involuntary spasm of muscles may occur as a part of the response to disease or injury in any part of the body, being a simple protective reflex designed to prevent movement and confer rest. Tonic or clonic spasm may also be encountered in a variety of nervous diseases described in other parts of this volume. In some instances, however, localised muscular spasm may occur as an isolated symptom. Two of these, facial spasm and hiccup, will be discussed here.

Facial Spasm. This is a condition of obscure origin occasionally seen in persons past middle age. The spasm, which is mainly of the clonic variety, first affects the orbicularis palpebrarum, but is apt with time to spread to the other muscles supplied by the seventh nerve. The frontalis and obicularis oris, however, usually escape. At rest there may appear to be some tonic overaction of the side of the face affected, but on voluntary movement to request this side is seen to be slightly the weaker. The clonic spasms are intermittent and irregular, and are increased by fatigue and nervousness. They are quite painless, but may give rise to worry and discomfort. The condition is always in the first phase, unilateral, but may ultimately involve the other side.

Diagnosis. This must be made from such gross causes of irritation of the seventh nerve as tumour or meningeal inflammation within the cranium, bony disease, or the pressure of an enlarged gland. True facial spasm may be distinguished from these by its protracted painless course and the absence of other physical signs.

Treatment. In an early or mild case relief from mental stress, together with sedatives, such as bromide or luminal in small doses, may bring about improvement. Many persons, even if the condition is severe or continuous, learn to ignore it. For those who are willing to accept a facial palsy instead of the spasm, the nerve may be injected with alcohol as it emerges from the stylo-mastoid foramen. The effect, however, wears off and the injection needs to be repeated every six to twelve months.

Hiccup. This is due to a spasmodic contraction of the diaphragm, causing an abrupt inspiration which is cut short by a sudden closure of the glottis. Hiccup is usually due to some recognisable cause in the way of visceral distension or irritation, either below or above the diaphragm. It may also be caused by irritation of the phrenic nerve, and sometimes by disease or poisoning of the nervous centres in spinal cord or medulla. It may also occur from excessive laughter, and sometimes for no apparent cause. It may in rare instances persist for several days and in itself demand treatment. It may often be stopped by holding the breath. In more obstinate cases a paroxysm of sneezing, induced by tickling the nose, or a whiff of snuff or pepper, may be effective. Other remedies which have been advocated are atropine $\frac{1}{100}$ grain, hypodermically, to be repeated in four hours if necessary, hyoscine hydrobromide $\frac{1}{100}$ grain, hypodermically, inhalation of a capsule of amyl nitrite, or a hypodermic of morphia. The passage of a stomach tube or inhalation of a mixture of carbon dioxide with air or oxygen may be successful in stopping a refractory attack.

DISEASES OF THE SPINAL CORD

For the proper understanding of this group of diseases an acquaintance with the principles of physiology and anatomy summarised on pp. 593 *et seq.* is essential.

Primary Disease of the Neurons. The several groups of neurons in the spinal cord may be separately affected by degeneration or disease. Such degeneration is the result of toxins, or is due to congenital want of vitality, or remains entirely unaccounted for. The lesions have been known as *tract diseases* or *system diseases*, and the following are instances: tabes dorsalis, in which the posterior columns are diseased; primary lateral sclerosis—pyramidal tracts; subacute combined degeneration—posterior columns and pyramidal tracts; Friedreich's disease—posterior columns, pyramidal tracts and spino-cerebellar tracts; progressive muscular atrophy—anterior horn cells; amyotrophic lateral sclerosis—anterior horn cells and pyramidal tracts.

Transverse Lesions. The spinal cord, having an elongated form, is naturally liable to lesions affecting its whole thickness, such as may occur from trauma, localised external pressure, the indiscriminate growth of tumour, the diffuse spread of inflammation, or the anæmia of vascular obstruction. In such cases grey and white matters are equally affected.

COMPRESSION OF THE SPINAL CORD

The spinal cord, on account of its soft consistency, is subject to compression as the result of disease or injury of neighbouring parts. The pathological changes which take place under such circumstances are the same whatever the actual cause. The symptoms, which are those of a transverse lesion, naturally vary with the level of the lesion. Other variations may be due to the rapidity with which the compressing force acts, and to the actual nature of the compressing cause.

Ætiology. The causes of spinal compression may be divided into: (a) disease of the vertebral column, (b) disease of the extra-dural space and meninges.

(a) *Disease of the Vertebral Column.* The spinal cord is frequently compressed suddenly as the result of *injury* with fracture dislocation. Of causes acting more slowly the commonest are *tuberculous caries* of the vertebræ or *new growths*.

(b) *Disease of the Extra-dural Space and Meninges.* *Injury* may occasionally result in hæmorrhage into the meninges, with subsequent cicatrisation and compression. Commoner causes of cicatricial constriction are a localised *syphilitic meningitis*; or a preceding *suppurative meningitis*.

New growths of various kinds may arise in the extra-dural space, in the meninges, or upon the nerve roots.

Morbid Anatomy. Sudden compression of the spinal cord, such as occurs from a fracture dislocation or the sudden collapse of a vertebra infiltrated by growth, results in acute necrosis of the part compressed from cutting off of the blood supply. With this are associated hæmorrhages from ruptured veins and capillaries. The dead tissues rapidly undergo fatty degeneration, with resultant softening, and this softening may spread in an upward or downward direction some distance beyond the level of the lesion.

Following the transverse lesion there is secondary degeneration of the nerve fibres which are cut off from their cells of origin (see Plate 51).

When the compression is more gradual the effect at first appears to be mechanical; the function of the compressed fibres is impaired, but rapidly returns if the pressure is removed. Later there is circulatory stagnation and œdema from compression of the veins, and finally obstruction of the arteries leads to necrosis and softening.

Compression of the spinal cord, whatever its cause, is likely also to produce obstruction of the sub-arachnoid space. This results in stagnation of the cerebro-spinal fluid below the blockage, with accumulation of protein, and to this is sometimes added a yellow pigment probably derived from extravasated blood.

Tuberculous caries of the vertebræ may cause compression of the cord in two different ways. The commoner mode is that in which the infective process makes its way through the posterior wall of the vertebra and forms a caseous abscess separated from the meninges by the extra-dural tissues. The formation of such

an abscess may occupy only a few weeks, and is quite commonly preceded by a history of injury to the diseased spine.

In the other form of tuberculous compression the infective process spreads directly to the meninges, causing a chronic localised meningitis, which in time constricts the cord. This process is very much slower than the other.

New growths in the vertebræ are usually of secondary origin, the commonest sources in the female being carcinoma of breast or uterus, and in the male the gastro-intestinal tract and prostate. The growth arises in the cancellous portion of the vertebra, which it erodes, until it finally bursts through the compact shell. The softening of the bone eventually leads to collapse of the walls of the vertebral canal with pressure upon the spinal cord. Often the vertebral column is much more extensively involved than may appear from the symptoms observed during life. Sarcoma may be primary or secondary in the vertebral column or the structures surrounding it, and results in changes similar to the effect of carcinoma. Myelomas in the vertebræ may also give rise to compression of the cord.

Paget's Disease of the spine may also cause compression of the cord.

The space between the vertebræ and the dura mater may occasionally be the site of tumours, usually of a sarcomatous nature, and may be a resting place for hydatid cysts. It is also sometimes invaded by Hodgkin's disease or lymphosarcoma originating in the mediastinum.

Chronic syphilitic meningitis may result in very great thickening of the meninges, in the midst of which the spinal cord is compressed. This is frequently associated with syphilitic disease of the arteries, which accelerates the process of necrosis.

Of *new growths of the meninges* the majority are small encapsuled tumours of benign type arising from the inner surface of the dura, the arachnoid, or the nerve roots. According to their microscopic appearance they are classified as endothelioma, psammoma, fibroma, fibro-myxoma and neurofibroma. This is the group of tumours which lend themselves readily to surgical removal.

The other type of growth met with in the meninges is of a diffuse sarcomatous nature, with a tendency to spread upwards and downwards, of malignant type and irremovable.

Meningitis serosa circumscripta is a title given to a condition in which the meninges are found matted together with inclusion of cyst-like spaces containing clear fluid. This may follow injury (often after a long latent interval) or may occur as a late result of suppurative meningitis, or it may be found without apparent cause.

Symptoms. The symptoms of spinal compression are those already described of a transverse lesion of the cord, varying with the level affected (*see* p. 607). To these must be added the symptoms due to compression of nerve roots when these are also involved.

When the compression occurs suddenly, as from fracture dislocation, or the collapse of a diseased vertebra, there is, in addition to the loss of sensibility, power, and sphincter control, an initial period of spinal shock during which all reflexes are abolished below the level of the lesion. With this there is often fever, and the clinical picture at first may resemble that of an acute myelitis.

When compression occurs gradually the first symptoms are often due to pressure upon posterior nerve roots. These take the form of pain, which is usually of a severe aching character, and is referred to the segmental distribution of the roots affected. As a rule it begins by being unilateral, but may later spread to the other side. Hyperæsthesia of the skin may sometimes be found in the area supplied by the irritated roots. Pressure upon anterior roots may also give rise to muscular wasting and weakness, which may be an important localising sign in compression of the cervical or lumbar enlargements.

It must be remembered, however, that in the thoracic region the vertical length of the segment is such that the cord may quite well be compressed without

involvement of nerve roots, and that in any case the compressing cause may act upon the anterior surface of the cord. In these cases the characteristic symptom of "root pain" is lacking from the history.

Of the structures within the cord the pyramidal fibres are usually the first to suffer, with resultant weakness and spasticity, increased tendon jerks, diminished or lost abdominal reflexes, and extensor plantar responses. Sensory disturbance is not as a rule evident for some time after weakness has been noticed. Careful examination is at first required for its detection. A level will be found below which pinprick is less painful, cotton wool touches are less constantly appreciated, and the difference between hot and cold tubes is less certainly distinguished.

Examination of the senses of positive and passive movement will reveal diminished accuracy, and the vibrating tuning-fork may be less keenly appreciated below a certain level.

As the disease progresses the sensory loss becomes more and more pronounced, until as a rule a definite border line may be distinguished between the healthy and the affected parts. This line, although it is not usually sharply defined, indicates fairly accurately the level of the lesion. It will occasionally be found that with a lesion in the upper region of the cord some of the fibres from the lowest segmental areas—and especially those conveying impression of deep sensibility—may escape, so that sensation to deep pressure is preserved over the sacrally supplied areas.

As the paralysis of the lower limbs increases control of the sphincters is impaired, with at first precipitate micturition and dyschezia.

Finally the compression, if not relieved, will lead to complete motor paralysis and sensory loss with abolition of sphincter control.

The details of the clinical picture will necessarily vary with the level of the lesion.

Additional evidence of spinal compression may be obtained by (1) examination of the cerebro-spinal fluid; (2) X-ray examination after the intrathecal injection of lipiodol.

(1) The cerebro-spinal fluid obtained from below the level of compression as a rule contains an excess of protein. This varies from a slight increase above the normal (0.025 per cent.) to amounts as high as 3 per cent., according to the degree and duration of the compression. When the protein content is extremely high the fluid often contains fibrinogen, and therefore may coagulate in the test tube. In addition, it sometimes exhibits a golden yellow tinge, due probably to the hæmolysis of blood transuded through the walls of obstructed veins.

If a manometer be employed to register the pressure of the fluid Queckenstedt's test should be employed (see p. 631). Under normal conditions compression of the jugular veins by an assistant will cause an immediate rise of pressure in the manometer. Absence of this rise indicates blockage of the subarachnoid space.

(2) The practice of injecting lipiodol introduced by Sicard is sometimes of value in confirming the clinical diagnosis of spinal compression and determining the upper level of the lesion. Lipiodol is a compound of iodine and fat, which is opaque to the X-rays, of a specific gravity higher than that of the cerebro-spinal fluid, and with little injurious effect upon the tissues.

One or two c.c. of this substance are injected into the cisterna magna with the patient in the sitting posture; immediately after the injection, while still in the erect position, he is X-rayed, and pictures taken both at the level of the presumed compression and of the lumbo-sacral spine. The X-ray examination is repeated half an hour later, and if necessary again after an interval of a few hours. Under normal conditions the lipiodol falls within a few minutes to the bottom of the thecal sac, where it is visible upon the X-ray plate at the lower border of the first sacral vertebra. It has been found that the irritative effect of lipiodol may cause an exacerbation of root pains, and may even lead to a temporary

increase in the signs of spinal cord compression. It should therefore be employed only when the diagnosis or localisation cannot be arrived at with sufficient accuracy upon clinical grounds (*see* Plate 52, Fig. 1). If the subarachnoid cavity is blocked, as must occur in an advanced case of spinal compression, the lipiodol is held up. In the illustration shown (Plate 52, Fig. 2) the block is at the upper border of the second lumbar vertebra. The cauda equina below this level was compressed by a large meningeal tumour of a fibromatous nature.

A more recent, safer and better method of employing lipiodol involves the use of an X-ray table upon which the patient can be tilted into a vertical position head downwards. The lipiodol is injected by lumbar puncture and its passage watched on the screen. By this means partial arrest can be observed.

These special methods of investigation are of great value, but it is not to be supposed that they will yield positive results until the degree of compression is considerable. There may therefore be a period in the early stages of the disease during which the clinical history and symptoms are the only guide to the nature of the case.

To the symptoms described above, which are common to all cases of compression, may be added those which belong to the compressing cause.

Disease of the vertebræ is commonly—but not always—associated with complaint of *local pain*, accompanied by rigidity and aggravated by any circumstance which tends to strain or jar the affected parts, such as stooping, jumping downstairs, or jolting over rough roads in a motor car. *Tenderness* and *deformity* of the diseased vertebræ are sometimes present. Finally the X-ray plate as a rule serves to demonstrate the presence of bony disease.

Chronic inflammation of the meninges as a rule involves several pairs of nerve roots. Root pain, therefore, is usually a prominent symptom and is often associated with reflex spasm of the back muscles leading to local rigidity of the spine.

New growths of the extra-dural space or meninges may cause no symptoms beyond those of simple compression, with or without root pains; they may, however, give rise to some tenderness of the overlying vertebra and reflex spasm of the muscles.

Diagnosis. This includes (1) the differentiation of spinal compression from other cases of transverse lesion; (2) the differential diagnosis of the causes of compression.

(1) Spinal compression of acute onset, as from a malignant growth, has to be distinguished from *acute myelitis*; here the chief points in favour of the former diagnosis are the presence of malignant disease elsewhere, and the characteristic changes in the cerebro-spinal fluid already described.

The more gradual cases of compression have to be distinguished from *intra-medullary tumour*, *disseminated sclerosis*, *syphilitic myelitis*, *amyotrophic lateral sclerosis*, *syringomyelia*, and *subacute combined degeneration*.

From intra-medullary tumour the differential diagnosis may be possible only at operation; in disseminated sclerosis the presence of scattered lesions as shown in signs or history usually gives the clue, but in certain cases the problem can be solved only by an exploratory laminectomy. Syphilitic myelitis will be recognised if the Wassermann reaction in blood and spinal fluid be included in the routine examination. The absence of sensory changes in amyotrophic lateral sclerosis and the presence of characteristic disorders of sensation in syringomyelia and subacute combined degeneration serve to distinguish these. Finally, the examination of the cerebro-spinal fluid and X-ray examination with lipiodol are often of differential value.

(2) The exact cause of compression can be discovered only by systematic investigation; in the absence of clinical or X-ray evidence of vertebral disease, and with negative Wassermann reactions in blood and spinal fluid, exploratory laminectomy should be undertaken.

The **Prognosis** depends chiefly upon the cause of compression. In cases of injury the cord itself as a rule is so severely damaged by the impact that decompression has little effect in producing amelioration of symptoms.

In most cases of tuberculous caries the prognosis is good with adequate treatment provided there is no active tuberculous disease elsewhere. In those cases, however, in which the gradually progressive history indicates a chronic tuberculous meningitis, the outlook is less hopeful. Malignant growths of the vertebræ may continue for months or years before finally causing death from bedsores and cystitis.

The progress of syphilitic meningitis may be arrested by suitable treatment. In meningitis serosa circumscripta division of the adhesions relieves the compression, but the condition is apt to recur. Intrathecal growths of the benign type may be completely removed.

In all cases in which the compressing cause can be removed, whether by means of rest in tuberculous disease or by operation, the degree of recovery which may be expected is proportional to the severity and duration of the symptoms. Total loss of power and sensibility in the lower limbs, provided it has not lasted more than a few weeks, is compatible with complete functional recovery. Once sphincter control is lost the chances of recovery are diminished owing to the complicating factor of urinary sepsis.

Treatment. The object of *radical treatment* is to relieve the compression. In the case of new growths this can be achieved only by surgical intervention. Benign tumours can be completely removed, and in some cases of malignant disease decompression may relieve pain.

Tuberculous caries is best treated by means of absolute rest in hygienic surroundings. The patient is laid upon a firm bed and extension maintained by traction upon the feet and chin; or he may be fitted from the first with a plaster jacket. Complete rest in the horizontal position should be maintained for at least a year. Subsequently the patient may be fixed in a plaster jacket and allowed gradually to resume the erect posture. Improvement in the signs of spinal compression may be delayed for several months, but as a rule these cases do well eventually.

Compression from syphilitic meningitis must be treated energetically with the anti-syphilitic remedies (*see* p. 666). If after a sufficient course there is no improvement, operation may be performed in the hope of dividing a cicatricial constriction. The meningeal adhesions resulting from trauma or suppuration should be treated in similar fashion by operation.

Palliative treatment in cases of transverse lesion of the spinal cord, whether due to compression or other causes, is directed towards preserving the anæsthetic skin from ulceration, draining and irrigating the bladder, providing relief from pain and discomfort, and preventing or remedying the contracture of spastic muscles.

For preservation of the skin the patient should be laid upon a water bed. The back should be washed night and morning, and whenever any soiling occurs; after washing and drying, the skin covering the bony prominences (including the heels) should receive a firm and prolonged rubbing from the palm of the hand. A dusting powder of chalk and boric acid should then be used. Care should be taken to avoid sodden or wrinkled sheets likely to produce excoriation, and the patient's position should be changed from time to time during the day in order to avoid constant pressure upon the same bony points. To move the patient two nurses are necessary if he is to be rolled, not dragged.

Should bedsores develop they should be dressed at suitable intervals; stimulant lotions and ointments may be used in succession; of the former Eusol (1 in 2,000) and Lotio Rubra are satisfactory; of the emollients equal parts of Ol. Ricini and Ung. Zinci or of Ol. Ricini and Tinct. Benzoini Co. are the most useful. Should the bladder be paralysed and retention of urine occur, cystitis almost

inevitably follows. It may, however, be kept in check by the following measures :

Either a catheter should be passed at six-hourly intervals or the instrument should be tied in and changed at intervals of three or four days. Before the catheter is passed not only should the glans penis be scrupulously cleaned, but the anterior urethra should be washed out with an antiseptic solution. The bladder should also be irrigated night and morning with an antiseptic fluid. Oxycyanide of mercury (1 in 4,000) is satisfactory, or if the urine is strongly alkaline a saturated solution of boric acid with an equal part of water may be used. In such cases also urotropin and acid sodium phosphate should be given by the mouth.

During irrigation care should be taken that sufficient fluid is not injected to cause over-distension, the correct amount being not more than 6 oz. When automatic emptying develops the irrigating fluid should be introduced under the least possible pressure and the bladder allowed to expel its contents if the reflex is evoked. It is not safe, however, to discontinue catheterisation until the bladder appears able to expel its contents completely without residual urine (2). Evacuation of the bowels should be managed with an enema every forty-eight hours, which minimises soiling ; if necessary, a carefully timed aperient of senna pods may be given beforehand.

Reflex spasms of the limbs, which are not only uncomfortable in themselves, but tend to produce bedsores from friction, may be relieved to some extent by a cradle over the lower limbs to prevent contact with the bedclothes. The temperature within this cradle should be maintained at a constant level by means of hot-water bottles. If these measures are of no avail, sedatives, such as luminal, in doses of 1 grain thrice daily, may be employed, or a larger dose may be given at night time.

The onset of contractures should be guarded against by daily passive movements and splinting so long as there is any hope of ultimate recovery.

The electric current should be reserved for such muscles as are wasted and paralysed from involvement of their lower motor neuron supply.

In old standing cases, when spontaneous improvement can no longer be expected, spasticity of the lower limbs may be relieved by section of the posterior nerve roots (Förster's operation). Laminectomy is performed and alternate roots are divided from the second lumbar downwards. This is necessarily a severe operation, and should not be undertaken except in especially favourable circumstances. Adductor spasm of the thighs may be treated by the simpler operation of cutting the obturator nerves, which sometimes gives great relief from discomfort.

TUMOURS OF THE SPINAL CORD

(Intra-medullary Tumours)

Tumours arising from the meninges and nerve roots have already been considered in the preceding pages, as causing compression of the spinal cord. Tumours within the substance of the spinal cord are relatively uncommon.

Pathology. They are more commonly found in the cervical and lumbosacral enlargements than at other levels. The usual type is the glioma. Sarcoma tuberculoma and gumma may also occur.

Symptoms. The symptoms of an intra-medullary tumour are those of a gradually progressive transverse lesion of the cord (*see p. 607*). In contradistinction to cases of spinal compression root pains are absent, and the early symptoms, therefore, are complaint of numbness and weakness in the extremities. Other symptoms vary with the level of the lesion. When this lies in the cervical or lumbar enlargements muscular atrophy from destruction of the anterior horn cells is a prominent feature. Partial destruction of the pain-conducting fibres sometimes causes complaint of painful paræsthesiæ below the level of the tumour. In

the early stages the subarachnoid space remains free, the cerebro-spinal fluid shows no increase of protein, and lipiodol injected into the cisterna magna is not held up. Eventually, however, the tumour may produce sufficient swelling of the cord to produce obstruction, and these tests will give positive results.

Diagnosis. The differential diagnosis presents much the same problems as that of spinal compression (*see* p. 659). It may be impossible to distinguish clinically between an intra-medullary tumour and syringomyelia, an accurate diagnosis being achieved only as the result of exploratory laminectomy.

Prognosis and Treatment. Some relief may be obtained from decompression, but the growth being as a rule of an infiltrating character is irremovable, and the ultimate prognosis bad.

Deep X-ray therapy should be tried when an accurate diagnosis has been made. Palliative treatment is the same as for other cases of transverse lesion, and has already been described under spinal compression.

MYELITIS

This term is used to denote an inflammatory process occurring within the substance of the spinal cord and involving all the constituents—blood vessels, nerve cells and fibres, and neuroglia—of the part affected.

Ætiology. It is assumed that in every instance the process of inflammation is due to bacterial agents, but in a number of the cases the causal organism remains unidentified. The spirochæte of syphilis, however, is responsible for a large majority, as proved by the history of primary infection, by the Wassermann reaction in blood and cerebro-spinal fluid, with increase of lymphocytes in the latter, and by histological examination of the spinal cord *post mortem*.

Apart from syphilis, several of the acute specific fevers may be complicated by the occurrence of myelitis, which is usually accompanied by signs of encephalitis. Of these the most important are measles, small-pox and chicken-pox. Myelitis may also occur together with encephalitis after vaccination.

In cases of this type the infective agents are presumably carried to the spinal cord by way of the blood stream. In other instances it is possible that organisms may reach the cord from some peripheral focus of sepsis through the pathway afforded by the perineural lymphatics.

To these may be added a group of cases in which the invasion of the cord by micro-organisms is secondary to an affection of the meninges. A greater or less degree of myelitis of such an origin may occur in meningitis due to tubercle bacillus, or to various other organisms, such as the pneumococcus, streptococcus and staphylococcus. In some cases the inflammatory process may spread directly from neighbouring structures, involving the meninges *en route*, as in the case of an ulcerating bed sore.

From the pathological standpoint it is convenient to differentiate between *acute infective myelitis* and *syphilitic myelitis*.

Morbid Anatomy. In *acute infective myelitis* the cord is softened and bulges on transverse section, or may be quite diffuent; but previous to section it may seem hard, from mere tenseness of the membrane containing the swollen cord.¹ To the naked eye the section is congested, minute vessels are visible, especially in the grey matter, and this itself is darker than usual, and its outline is indistinct. Patches of grey tint may be present in the white column, or the whole surface is confused. Under the microscope, in early stages, are found perhaps capillary hæmorrhages, and leucocytes in the lymphatic sheaths and around the vessels. The nerve fibres suffer by breaking up of their myelin sheaths, and here and there occurs a fusiform enlargement of the axis cylinders, which in its thickest part is five or six times the diameter of the normal fibre; this may

¹ Any cord may become soft from decomposition, or may be reduced to a pulp by clumsiness in extracting it from the spinal column.

be due to imbibition of fluid. The nerve cells are swollen, granular, with perhaps fatty globules, and some of them undergo vacuolation. Subsequently both nerve cells and fibres undergo fatty degeneration, and the degeneration products are removed by scavenging cells of neuroglial or vascular origin. There is at the same time an increased growth of neuroglial fibres, so that the end result is a sclerosis of the parts affected.

The lesion may be confined to a few segments (*transverse myelitis*), it may be quite diffuse, affecting a considerable length of the cord (*diffuse myelitis*), or there may be several areas of inflammatory softening, separated by areas of healthy tissue (*disseminated myelitis*).

Syphilitic Myelitis. In this condition the spinal cord may be affected in different ways. On the one hand, syphilitic disease of the vessels may lead to thrombosis and so to softening of the nervous substance, while, on the other hand, gummatous thickening of the meninges may eventually cause compression of the spinal cord, with consequent degeneration of the part encircled. In most cases the condition found is a combination of these two processes, which should be spoken of more correctly as a *syphilitic meningo-myelitis*. Probably the specific toxins of the syphilitic virus also play a part in causing the degenerative changes.

The process is generally limited to a few segments, thus resulting in a transverse lesion of the cord. The blood vessels may show cellular infiltration of the adventitial sheath, together with thickening of the intima, which has sufficed to occlude the lumina. In this case there is complete disintegration and liquefaction of the area supplied by them. Or the appearance may correspond more nearly with that of an inflammatory lesion. There may be no endarteritis in this case, but the vessels are completely surrounded with cellular exudate, which may extend into the surrounding tissues, and is accompanied by degeneration of the nerve elements, apparently of a toxic nature. The leptomeninges are in almost all cases infiltrated with mononuclear cells, and in some instances the dura mater is also involved and may be greatly thickened, so that the whole cord is surrounded by a band of dense fibrous tissue, which in its turn may lead to occlusion of blood vessels by pressure, and so to central softening. Where the meninges are extensively affected the nerve roots become involved in the inflammatory mass, with resultant degeneration of their fibres.

Symptoms. These depend rather upon the localisation of the lesion than upon its pathology. It is useful, however, to distinguish between an *acute* and a *chronic* form of the disease.

Acute Myelitis may be either of syphilitic or of general infective origin. The *syphilitic* variety of acute myelitis occurs more commonly in males than females, generally in young adults with a history of primary syphilis a few years previously. The symptoms are probably due in most cases to the sudden occlusion of thickened vessels with consequent softening of the spinal cord. The onset, therefore, is frequently sudden, paralysis and anæsthesia occurring without warning and without pain, unless, as sometimes happens, the vascular disease is associated with extensive meningeal involvement, in which case there will probably have been previous complaint of pain in the distribution of the posterior roots affected. There is little or no constitutional disturbance. Examination of the cerebro-spinal fluid reveals an excess of cells and albumin with a positive Wassermann reaction. The Wassermann reaction is as a rule positive also in the blood.

Acute infective myelitis may occur at any age without especial relation to sex, but is most often seen in young adults. It is a comparatively rare disease. At the onset there are usually signs of constitutional disturbance, such as headache, pains in the limbs, anorexia and general malaise, with pyrexia of varying degree, and occasionally rigors.

The nervous symptoms may develop suddenly with paralysis and anæsthesia

below the level of the lesion, but more usually some days elapse before the acme of the disease is reached. The early symptoms are numbness and tingling in the extremities and slight degrees of motor weakness, together with impairment of sphincter control. Pain is but slight as a rule, but there may be complaint of a dull ache in the back, or a girdle sensation around the chest or abdomen. With the further development of the disease paralysis and loss of sensation generally become complete up to the level of the lesion, and this may progress in an upward direction (*acute ascending myelitis*). There is complete loss of control over the sphincters, bedsores rapidly develop, the pyrexia continues, and the illness progresses after a variable time to a fatal issue, or more rarely it may become arrested with some degree of recovery.

Acute Disseminated Myelitis is a comparatively rare and fatal variety of the infective form, characterised by the simultaneous occurrence of symptoms referable to lesions scattered throughout the cerebro-spinal axis, together with signs of severe constitutional disturbance, and in a number of cases optic neuritis, retro-bulbar neuritis or papillitis.

In all forms of infective myelitis examination of the cerebro-spinal fluid may show an excess of cells, comprising lymphocytes, polymorphs, or a mixture of both. In many cases, however, the fluid shows surprisingly little abnormality.

The **physical signs** in a case of acute myelitis naturally vary with the level of the lesion and with its extent (*see* p. 607).

Death in cases of acute myelitis or softening takes place (1) from pulmonary complications following upon paralysis of the respiratory muscles; (2) from bedsores intensifying exhaustion, or leading to pyæmia; (3) from vesical complications; (4) from intercurrent affections, such as pneumonia or bronchitis. The bladder is extremely liable to cystitis, partly from trophic disturbance, partly from retention of urine; and the use of the catheter may be responsible for the introduction of organisms which set up septic inflammation. When cystitis occurs the urine rapidly decomposes and becomes ammoniacal, unless it is repeatedly removed by the catheter; it contains pus or muco-pus, and readily deposits crystals of ammonium-magnesium phosphate on standing. Almost at any time the septic condition of the bladder may extend up the ureters to the kidneys, and suppurative pyelitis and nephritis will then occur, and the patient may die with uræmic symptoms.

Cases which escape these dangers generally lapse into a chronic condition, which may be of indefinite duration, but sometimes recovery slowly takes place after many months. A small number of cases get well comparatively quickly, and these are more common among the milder cases of myelitis following infectious disorders.

Cases of syphilitic origin frequently recover under proper treatment, but there is usually a more or less serious degree of residual paralysis with imperfect control over the sphincters.

Chronic Myelitis is almost always of syphilitic origin. The process is one of gradual compression of the spinal cord and its vessels by gummatous thickening of the meninges, together with a certain amount of toxic degeneration of the nerve cells and fibres due to the syphilitic poison. The symptoms therefore are those of a localised spinal meningitis with involvement of nerve roots, to which are added those of compression of the spinal cord. The main feature of these cases in their early stages is the pain due to involvement of the posterior roots. This is of a shooting nature, and if, as frequently occurs, the lesion is in the mid-dorsal region, the pain, as a rule, begins in the back and radiates around the trunk on one or both sides; if the cervical region is affected, the pain will be experienced in the length of one or both arms, and will be accompanied by muscular paralysis and atrophy due to involvement of the motor nerve roots (*see* Internal Pachymeningitis). These symptoms of root irritation and destruction may exist for some

months before the spinal cord is seriously involved. The symptoms of a transverse lesion of the cord appear gradually, beginning with a transient weakness or numbness of the lower extremities, together with a difficulty in controlling the sphincters, progressing in a few weeks to a condition of spastic paraplegia with increased tendon jerks and extensor plantar responses. The loss of power and sensibility is not as a rule complete.

If the lesion is situated in the lumbo-sacral enlargement, the most prominent symptoms are pain in the distribution of the sacral nerve roots together with disturbance of sphincter control.

It is not possible to draw any hard and fast line between cases of acute and chronic syphilitic myelitis of the types described above : disease of the vessel walls is an almost constant feature, so that in a case which has begun with symptoms of gummatous meningitis the signs of a transverse lesion of the cord may develop rapidly as the result of thrombotic softening.

Another somewhat rare form of syphilitic myelitis is that in which the pyramidal tracts alone are affected by the specific toxins, resulting in a gradually progressive motor paralysis of the lower limbs with increase of the deep reflexes, extensor plantar responses and spasticity. This is known as *Erb's syphilitic paraplegia*.

Another rare and obscure disease, known as *toxic myelitis*, is especially associated with pregnancy. The symptoms are those of a gradually progressive transverse lesion of the cord, which is not complete, and the tendency is towards spontaneous recovery. The condition may clear up completely after confinement and recur with subsequent pregnancies.

Diagnosis. The recognition of the acute infective form of myelitis is as a rule not difficult in view of the pyrexia and constitutional disturbance. It must be recognised, however, that such signs of general illness may be present in cases of tuberculous caries or malignant growth of the vertebræ, in which sometimes the onset of signs of compression of the spinal cord may be quite sudden. Careful examination of the vertebral column, together with an X-ray picture of that part of the bony canal which encloses the affected segment, suffices as a rule to differentiate these cases. Acute poliomyelitis and Landry's paralysis may be distinguished by the absence of sensory loss and sphincter involvement.

Both the acute and especially the chronic forms of syphilitic myelitis have to be distinguished from compression of the spinal cord by tumours of the membranes or the vertebræ or by spinal caries. Here again the X-ray plate will help to exclude vertebral disease, whilst in the syphilitic cases the cerebro-spinal fluid constantly shows an increase of cells and albumin, together with a positive Wassermann reaction. The latter is positive also in the blood. Myelitis may sometimes be confused with peripheral neuritis, but in the latter condition there is no disturbance of sphincter control, the weakness involves both upper and lower limbs before it affects the trunk, and the sensory disturbance, when present, has a peripheral nerve distribution.

An extensive patch of disseminated sclerosis may produce all the signs of an acute myelitis, but there is no severe constitutional disturbance such as occurs in the acute infective conditions ; examination of the cerebro-spinal fluid serves to exclude syphilis ; and a careful review of the history with perhaps the presence of other signs, such as nystagmus, will make clear the diagnosis.

Prognosis. Complete recovery is the exception, except in those cases which follow measles or chicken-pox, in which the prognosis is very favourable. Most of the syphilitic cases make considerable improvement under proper treatment, but there is always a residue of paralysis, usually associated with impairment of sphincter control. Many of the cases of acute infective myelitis progress to a fatal issue either in the early stages from the severity of the initial illness or later from urinary sepsis or bedsores.

Treatment. The general treatment of a case of myelitis is the same as that

of any transverse lesion of the cord, and has already been described under the heading of compression lesions (p. 660).

Treatment of Syphilitic Myelitis. In cases due to syphilis, salvarsan should be given, and a course of mercury and potassium iodide should be instituted, and continued over a long period. There is some diversity of opinion as to the dosage of salvarsan which should be employed. It appears, however, that for the efficient treatment of syphilis of the nervous system larger doses are required than in the case of syphilis elsewhere, and that patients suffering from this form of the disease are relatively tolerant of the drug.

The following course is recommended: The initial dose of novarsenobillon for an adult male should be 0.45 gramme intravenously, followed after a week's interval by 0.6 gramme, and subsequently by six further doses of 0.6 gramme at weekly intervals. An interval of eight weeks should then be allowed to elapse before any more novarsenobillon is given in order to guard against the dangers of delayed arsenical poisoning. During this period a weekly dose of bismuth (*e.g.* stabismol 2 c.c.) should be given by intramuscular injection. The intravenous injections are then begun again with a dose of 0.6 gramme followed by six further doses of 0.6 gramme at weekly intervals. Throughout this course of treatment mercury and iodide should be given by the mouth. A mixture containing 1 drachm of the liquor hydrarg. perchlor. and 15 grains of pot. iod. t.d.s. p.e. is suitable. The patient should be instructed to take particular care in cleaning his teeth while under this treatment on account of the liability of persons taking mercury or bismuth to develop septic conditions of the gums and mouth. If symptoms of this kind arise treatment by these drugs must be suspended for the time being.

One month after the completion of the course the Wassermann reaction may again be tested in the blood and cerebro-spinal fluid, but even if this is negative the patient should not be considered "cured"; if the progress of the disease appears to have been arrested, he may discard treatment for the time being, but whether the Wassermann reaction is positive or negative, he should submit himself annually to a short course of further treatment, which may consist of four weekly injections of novarsenobillon 0.6 gramme, together with the mercury and iodide mixture thrice daily during the month.

In any case in which, at the end of the initial course, symptoms appear to be actively progressing, treatment should be recommenced on the same lines after a suitable interval, while a careful watch should be kept for any symptoms of arsenical poisoning. The dosage of novarsenobillon described above is that recommended for a healthy adult male. In the treatment of individual cases the dose to be employed must be carefully considered in relation to the general condition of the patient, and it should be remembered that some persons are intolerant of arsenic in much smaller quantities than those recommended. The early signs of poisoning to be looked for are severe constitutional disturbance within twenty-four hours of each injection, continuous malaise and gastro-intestinal irritability, jaundice and skin disturbances such as erythema and exfoliative dermatitis. The occurrence of any such symptoms is a warning to discontinue arsenical treatment at once (*see* p. 117).

HÆMORRHAGE INTO THE SPINAL CORD

(*Hæmatomyelia*)

This is a very rare occurrence, and contrasts remarkably with hæmorrhage into the brain, which is one of the most common causes of cerebral paralysis.

Ætiology. It is in almost all cases the result of injury, either from direct violence applied to the spine, or less directly from a fall upon the feet or head. In the last instance, when associated with symptoms of cerebral concussion or contusion, its symptoms may easily escape recognition. The cervical region of the

cord is the part most commonly affected, and the hæmorrhage is generally confined to the grey matter. Rare instances of "spontaneous" hæmatomyelia have been recorded, and hæmorrhage may also occur into a pre-existing syringomyelic cavity.

In the great majority of the traumatic cases the lesion is in the lower part of the cervical enlargement, and the injury has been caused by force applied to the top of the head with violent flexion of the neck. It is probable that in most of these cases the spinal cord is damaged by momentary compression from a fracture-dislocation of the cervical spine. The contusion which results from such injury has its maximal disruptive effect in the central grey matter of the cord.

Symptoms. The symptoms of a severe hæmatomyelia in the early stages are indistinguishable from those of a transverse lesion of the cord, for the hæmorrhage, though confined to the grey matter, compresses the longitudinal fibres around it. When the effect of this has passed off the results of the damage to the grey matter are evident in the form of wasting and weakness of the muscles supplied by the anterior horn cells of the segments involved and a dissociated anæsthesia below this level, sensibility to pain and temperature being affected without loss of the tactile or postural senses.

Diagnosis. The diagnosis in traumatic cases has to be made from a compression lesion of the cord. The presence of deformity of a degree sufficient to cause compression may be determined by clinical and X-ray examination, and evidence of sub-arachnoid block, obtained from lumbar puncture, will clinch the point. In the rare spontaneous cases the sudden onset suffices to distinguish the condition from that of syringomyelia and the dissociated nature of the sensory loss from a transverse myelitis.

Prognosis. Death is rarely caused by the primary lesion if the patient survives the first few hours; later urinary sepsis or bedsores may lead to a fatal issue. Some degree of recovery may be expected in almost all cases, and the final prognosis may be gauged in some measure by the rate of progress in the early stages. If improvement in power sensibility and bladder control manifest themselves within a week or two of the injury, the outlook is good. If there is no return of power at the end of three months, the paralysis is likely to remain permanent. In all cases affecting the cervical enlargement the atrophic paralysis of the hands due to destruction of anterior horn cells is likely to persist in some degree as a permanent disability.

Treatment. Absolute rest is the first consideration. The patient should be laid flat, preferably on a water mattress, and the greatest care should be taken to avoid unnecessary movement. Provided that the respiratory function is not impaired, morphia should be administered freely during the first forty-eight hours to control restlessness. Massage, exercises and electrical treatment should be prohibited for at least three weeks.

DISSEMINATED SCLEROSIS

(Multiple Sclerosis, Insular Sclerosis, Sclérose en Plaques Disseminées)

This disease is characterised by the development of numerous patches of sclerosis throughout the brain and spinal cord.

Ætiology. The disease is somewhat more frequent in females than in males. The symptoms are mostly noted for the first time in youth or early adult life, and in 170 cases observed by the writer the onset in 67 per cent. occurred between the ages of twenty and forty. In 8.5 per cent. the age of onset was between fourteen and twenty, and in the remaining 24.5 per cent. over forty, the latest age being fifty-five. Although the pathological and clinical evidence suggests a toxic or infective agent as the cause of the disease, experimental researches upon its nature have so far yielded negative results. In a small proportion of cases

the disease occurs in several members of the same family, which suggests that constitutional liability may play a part in the ætiology.

Pathology. Though little can be said with certainty as to the origin of the disease, it is probable that toxins carried to them by the blood cause degeneration of the myelin sheaths and eventually of the axis cylinders, and that simultaneously, or somewhat later, hyperplasia of the neuroglia occurs, resulting ultimately in sclerosis.

Morbid Anatomy. The surface of the spinal cord, medulla oblongata, pons, and the base of the brain presents a number of irregular patches of pinkish-grey colour, rather sharply outlined and contrasting with the natural white colour of the medulla, pons, and crura. On section the discoloration is found to extend inwards so as to form deposits of a round or oval shape, ranging in size from that of a pea to that of a hazel-nut, generally harder than the normal nervous tissue, and even leathery or cartilaginous, sometimes projecting above the level of the section, sometimes sunken below it. Recent patches are dark grey, older patches more yellowish grey, and less translucent. They affect the white matter more than the grey matter; thus in the spinal cord the greater part of the cornua is unaffected, and in the cerebrum they are best seen on section of the hemispheres, which are dotted with the grey areas, and the walls of the lateral ventricles are often invaded. The Sylvian aqueduct also is commonly surrounded by areas of sclerosis. They are not frequent in the cerebellum, but may invade the olfactory bulbs and the spinal and cranial nerve roots. Under the microscope the outline of the patch or nodule is much less distinctly marked than it appears to the naked eye. The nodule consists chiefly of fibrous or finely fibrillated tissue, developed by overgrowth of the neuroglia; within this area the nerve fibres have lost their myelin sheaths, but many axis cylinders persist. The earliest stage of the lesions appears to be degeneration of the myelin sheaths, which become swollen and are then broken up into fatty droplets. The products of myelin degeneration act as an irritant, the neighbouring vessels become congested and there is perivascular infiltration with lymphocytes, polymorphonuclear and plasma cells. In the next stage large mononuclear cells appear which engulf the fatty droplets and convey them towards the venules. There is at the same time a reaction on the part of the surrounding glia cells (comparable with the connective tissue cell reaction around inflammatory foci elsewhere in the body). The axis cylinders suffer less severely than the myelin but are always involved in some degree, those affected becoming at first swollen in an irregular manner and finally disappearing. Finally, when the products of degeneration have been completely removed, a dense patch of glial overgrowth represents the scar of the original lesion. Owing to the excessive glia reaction, neighbouring foci tend to be bound together in a common sclerotic plaque which is visible to the naked eye.

In sections obtained by the Weigert-Pal method the healthy fibres are stained black, while the plaques of glial sclerosis, being left unstained, stand out in sharp contrast against the dark background (*see* Plate 53, Figs. 1 and 2).

Symptoms. The most characteristic feature of the illness in its early stages is the variety, and often the transient nature, of the symptoms, depending as they do upon a random and haphazard distribution throughout the cerebro-spinal axis of minute foci of the disease, each of which in its initial stages causes a much greater disturbance of function than ultimately persists. As the disease progresses, with the accumulation and coalescence of repeated patches of sclerosis, the total area of permanent damage steadily increases, so that the symptom picture becomes more uniform and more constant.

The manner of the onset is itself variable; most frequently it is somewhat sudden, with symptoms referable to a small lesion of the longitudinal fibre tracts, the optic nerves or the substance of the brain-stem. Thus the patient may complain of a numbness in some area of trunk or limbs, a dragging of one foot, some

slight difficulty in controlling the bladder, double vision, or a mistiness before one or other eye. Examination at the time may reveal slight evidence of organic damage, such as impairment of sensibility, inequality or absence of the abdominal reflexes, or an abnormal plantar response, but these signs, together with the symptoms, commonly disappear in the course of a few days or weeks, to be succeeded after a variable interval of quiescence by the development of new troubles elsewhere or renewal and intensification of the old. In other cases the symptoms begin more gradually, perhaps with progressive weakness or stiffness of one or both legs or an increasing tremor of the hand. Even of these cases, however, the majority show remissions and exacerbations, so that the course of the illness is seldom continuous.

The nature of the earliest symptoms depends upon the situation of the first patches of the disease, and is therefore variable in the extreme. It is to be remembered, however, that the morbid process chiefly involves the white matter of the cerebro-spinal axis; that, owing to the great length of the main sensory and motor tracts, these are most likely to suffer damage; and that on account of their functional importance such damage is most likely to result in symptoms. Moreover, on account of their greater length the fibres going to and coming from the lower limbs are more vulnerable than those connected with the arms.

The optic nerves, however, are affected with a frequency which is quite out of proportion to the space which they occupy in the white matter, and are often involved in the earliest stage of the disease. The most characteristic form of this involvement is an attack of retro-bulbar neuritis, usually confined to one eye. The patient becomes suddenly conscious of defective vision, and on closing the sound eye finds that his sight is seriously impaired. The onset is usually accompanied by pain in the eyeball, especially on movement, and the defect of vision may be progressive over a period of days. On examination of the fundus at this stage no abnormality is detected unless the lesion has extended forward as far as the papilla, when a variable degree of swelling (papillitis) is to be observed. Examination of the visual fields reveals a central scotoma, and, if this be large, with a correspondingly severe diminution of visual acuity, the reaction to light of the pupil on the affected side will be ill-sustained. After a variable period there is improvement of the visual function, often with a return to normal. Within a few weeks of the onset the pallor characteristic of optic atrophy is to be observed in the optic disc, particularly on its temporal side.

In a series of 139 cases of disseminated sclerosis collected by the writer, such an attack of retro-bulbar neuritis occurred at some time or another in 28 per cent., and in two-thirds of these cases it occurred, either alone or with other symptoms, as the first evidence of the disease. The affection of the optic nerves, however, as of other parts, may be gradual and insidious, so that it is not uncommon to observe optic atrophy in one or both eyes in a patient who can give no account of any sudden or severe disturbance of vision, and may be unaware that it is affected. Permanent impairment of vision in both eyes of any serious degree is fortunately extremely uncommon.

Not infrequently the first symptoms take the form of paræsthesiæ—that is, sensations of numbness, tingling, tightness, coldness or heat—referred to various areas of the trunk or limbs. Careful examination may reveal diminished cutaneous sensibility, but of more common occurrence are signs of damage to the posterior columns, revealed by impairment of the senses of position and passive movement, diminution or loss of the vibration sense, and in the hands astereognosis. In the arms extensive damage of this nature may give rise to symptoms which are somewhat characteristic and by no means uncommon. The patient complains that the hand is useless: he is unable to employ it usefully for purposes of eating, buttoning his clothes, and so on. Examination reveals no loss of power, and as a rule little or no impairment of tactile sensibility, but there is gross loss of sense of position, with consequent ataxia and astereognosis.

The commonest form of motor disturbance is weakness of one or both legs of the type due to pyramidal damage. Thus the group of muscles earliest affected is that of the dorsiflexors of the ankle, so that the foot drags along the ground, and this in the early stages may only be noticed after excessive exercise, as at the end of a long day's walking. With the weakness, which in more severe cases affects the flexors at knee and hip joints also, is associated spastic rigidity of the extensors, so that the patient may complain of stiffness rather than paralysis. With this also there is sometimes complaint of "cramps" in the legs, or of involuntary flexor movements, described as "jumping upward" of the lower limbs, which are especially likely to occur in bed at night.

When symptoms of this nature are prominent they are associated with the signs of a pyramidal lesion, namely, loss of the abdominal reflexes, exaggeration of knee and ankle jerks, and an extensor plantar response, which are most marked on the side chiefly affected.

In connection with involvement of the brain-stem reference has already been made to diplopia from involvement of the oculo-motor nuclei or nerve. This is nearly always of a quite transitory nature, lasting a few hours or a few days, and occurs at one time or another in about a third of the cases. It is often one of the earliest symptoms, and may be neglected at the time and afterwards be forgotten by the patient, unless his attention is specially called to the point.

Nystagmus, from interference with the fibres connecting the vestibular with the oculo-motor nuclei, is seldom noticed by the patient, but is present in more than three-quarters of the cases, often at an early stage. It is usually obtained only on lateral deviation of the eyes, is most commonly bilateral, and at first irregular, being well marked at some times, hardly to be noticed at others. It is, however, one of the most characteristic signs of the disease.

Motor inco-ordination of cerebellar type, probably attributable to lesions of the superior cerebellar peduncles at or near the point of their decussation, is sometimes an early symptom, and is present in about half the cases at some time. It is shown most frequently in the form of intention tremor of the arms, and a disturbance of the speech which depends upon inco-ordination of the articulatory musculature. The intention tremor is so called because it is not as a rule present when the arm is at rest, but is observed when the patient attempts to take hold of an object, or in the performance of the finger-nose-finger test. One limb oscillates irregularly to the right and left, or up and down, without regard to the object aimed at, and there is a tendency to overshoot the mark. In addition to this, a nodding, to-and-fro tremor of the unsupported head is frequently observed. The speech has been described as staccato, or scanning, and is of the type already described under Disturbances of Cerebellar Function (*see* p. 617).

As has already been noted, the cerebral hemispheres are commonly riddled with sclerotic patches, and to this must be ascribed the mental changes which are present in the majority of cases before the end, and are often noticeable at an early stage. They are of the general type occurring in other organic diseases of the brain, and consist of emotional instability and lack of control, indifference to the serious nature of the malady, lack of judgment in practical affairs, and defective memory. It is the combination of slight mental changes of this type with a history of transient weakness, or vague sensory disturbances, which so frequently leads to an erroneous diagnosis of hysteria in the early stages.

In addition to those already described, the disease may be ushered in by a variety of other symptoms of less common occurrence. Thus lesions of the cerebral hemispheres may give rise to hemiplegia of sudden or gradual onset, patches involving the central connections of the vestibular nerves may lead to attacks of giddiness or vertigo, or a predominant affection of the cerebellum may cause symptoms of pure cerebellar disease. There are also cases in which the morbid process begins in the lumbo-sacral enlargement, and loss of control over the sphincters is a prominent and early symptom.

In rare instances also the grey matter of the anterior cornua is affected, with resultant atrophy of the corresponding muscles, usually those of the hands.

The *course of the disease* is also variable. In a majority of cases the illness begins in a subacute manner—the patient suddenly notices a numbness of the hand or dragging of the foot—and its progress is characterised by a succession of remissions and exacerbations. The latter may be manifested in the form of new symptoms or intensification of those already present. The duration of the remissions is variable, but may extend over months or years. The writer has notes of a case in which there was an interval of twenty-four years between one exacerbation and the next. In some cases, however, the disease runs what appears to be a chronic and progressive course from the beginning. It is doubtful whether one can separate a chronic from a remittent type, for, on the one hand, a case which has begun in the more usual manner with remissions may finally become steadily progressive, and, on the other hand, there may be subacute exacerbations in the course of a case which has for some time shown a chronic progressive character.

In the *later stages* the patient becomes bedridden from paralysis of the lower limbs, which commonly develop the position of spasticity in flexion. Control over the sphincters is lost, and bedsores frequently develop. Even at this stage, however, tactile sensibility often remains unaffected, though examination with the tuning-fork usually reveals loss of the vibration sense in the lower limbs. The knee and ankle jerks may now be exaggerated or absent, the plantar responses are extensor, and the abdominal reflexes are lacking.

Diagnosis. There is no disease in which a carefully elicited history is of greater value. The diagnosis rests upon the proof of *multiple* lesions of the central nervous system, and this may only be forthcoming from a consideration of the story of a retro-bulbar neuritis or of a transient diplopia, numbness, or weakness in conjunction with the physical signs. The danger of a mistaken diagnosis of *hysteria* has already been mentioned. As a rule the detection of some slight sign of organic disease, such as nystagmus, absent abdominal reflexes, an extensor plantar response, or pallor of the optic discs, will permit of the differential diagnosis, but there are cases in the early stages in which it may sometimes be wiser to suspend judgment. The combination of nystagmus with tremor and inco-ordination of the arms may give rise to suspicion of *cerebellar tumour*. In the latter condition, however, the symptoms are all referable to a single lesion, and in the later stages there are symptoms of increased intracranial pressure. The spasticity and weakness of the lower limbs need to be distinguished from similar conditions arising from *compression of the spinal cord* by tumour or spinal caries.

Syphilis of the central nervous system in certain of its forms may give rise to a picture closely resembling that of multiple sclerosis, and in any case in which there is a doubt as to the diagnosis the Wassermann reaction should be done with blood and cerebro-spinal fluid. In disseminated sclerosis this reaction is uniformly negative, and the cerebro-spinal fluid does not often show changes in its cell or protein content. The colloidal gold curve, however, is often abnormal, resembling that found in neurosyphilis. Some cases of *encephalitis lethargica* in which the spinal cord is extensively involved may at first be mistaken for multiple sclerosis; this mistake is especially likely to occur with a case of encephalitis in which the illness is protracted with comparatively long remissions; the differential diagnosis may be made as a rule by careful consideration of the history of the case, particularly the nature of the onset and the occurrence of pyrexia or drowsiness in encephalitis.

The **Prognosis** is unfavourable. If the patient be seen in an acute exacerbation it may generally be said that some improvement will follow, but the great probability is that by the accumulation of repeated patches of the disease

he will finally become crippled and bedridden. Remissions simulating recovery are not uncommon and may last for years, but only in very rare instances has the progress of the illness seemed to be arrested.

Treatment. There is at present no specific remedy for the disease. Arsenic is of traditional repute as a medicine for it, and its use has been provided with some rational basis by the suspicion that disseminated sclerosis may be due to a chronic protozoal infection akin to syphilis. It may be given either by the mouth or by injection, the latter method being chosen for an acute exacerbation. In such case the patient should be put to bed as soon as the nature of the symptoms is recognised, and kept at rest for a fortnight or until the symptoms begin to improve. Three doses of Stabilarisan, 0.3 gramme, or an equivalent dose of some other suitable arsenical compound may be given by intramuscular injection at weekly intervals, and should be followed up by a mixture containing 3 to 5 minims of liquor arsenicalis by the mouth thrice daily after food. This may be continued for six weeks and repeated at intervals, as a measure of treatment or prophylaxis. The patient who has once manifested symptoms of the disease should lead a life as free as possible from physical and mental stress and from risk of cold and exposure. A sedentary occupation is indicated, both for its freedom from physical fatigue and the opportunity which it affords for continuing at work despite some degree of disability. In women the stress of pregnancy and confinement carries with it a risk of exacerbation, and the diagnosis of disseminated sclerosis provides a sound reason for abortion.

There is no doubt that in cases in which ideal conditions can be obtained the remissions are on the whole longer than in the others, though the relapses, when they occur, may be equally severe. Many patients in whom the disease is recognised and treated early, and who are able and willing to lead quiet and sedentary lives, may go years without relapse. Massage and graduated exercises are valuable in the treatment of motor symptoms, especially in the stage of recovery from an exacerbation. Hot baths followed by passive movements are useful for the relief of spasticity. A mixture containing 5 grains of potassium bromide and 10 minims of the tincture of belladonna given thrice daily is helpful for patients with precipitate micturition.

Palliative treatment in the later stages of the disease must be conducted on the same lines as those already prescribed for transverse lesions of the spinal cord (*see* p. 660).

SYRINGOMYELIA

This is a disease in which elongated cavities are formed in the centre of the cord as the result of a combined process of new growth and degeneration. The symptoms depend in the early stages upon destruction of the constituents of the grey matter; in the later stages the fibre tracts are also involved from pressure.

Ætiology. The disease occurs more commonly in men than women, and begins as a rule between the ages of twelve and thirty. It is sometimes associated with spina bifida, with cervical ribs or other congenital deformity.

Pathology. The essential feature of the disease is a new growth of glial tissue with subsequent degeneration and cavity formation. This begins as a rule in one of the posterior horns of grey matter close to the central canal and extends forward into the anterior horns, occluding, or sometimes communicating with, the central canal. There is a tendency for the morbid process to spread upwards and downwards in the cord, but the lumen of the tube thus formed may exhibit great variations at different levels (*see* Figs. 85, 86). The portions of the cord chiefly affected are the cervical and upper dorsal regions, the lumbar region and the medulla (syringobulbia).

The **Symptoms** in the early stages are referable to destruction of (1) the anterior horn cells; (2) the fibres conveying sensations of temperature and pain which decussate in the grey matter; (3) the cells of the lateral horn of grey

TABES DORSALIS

(Locomotor Ataxy)

Tabes dorsalis is essentially a gradual progressive degeneration of the lower afferent neurons, first manifesting itself in the posterior columns of the spinal cord; this is accompanied or followed by an overgrowth of the neuroglia. Similar changes may occur in the optic nerve, and in the central portions of the afferent cranial nerves. Tabes is therefore a disease affecting the sensory neurons, the disorder of locomotion from which it was originally named being due to loss of sensations of position and passive movement, with resultant inco-ordination of the movements in walking. Later experience shows that the ataxia is often a very late phenomenon, and, indeed, may be entirely absent; while there are other disturbances in the realm of sensation which are more constant, and provide the symptoms for which the patient usually first seeks medical advice.

Ætiology. That the sole cause of the disease is syphilis is now generally accepted. This opinion is founded upon evidence of primary infection in the past history of the patient; positive Wassermann reactions in blood and spinal fluid; and the presence of other syphilitic lesions (such as aortitis) in the body after death. One or other of these proofs is seldom if ever lacking when searched for. Noguchi first demonstrated the *Treponema pallidum* in the spinal cord from a case of tabes, and the observation has now been often repeated. Cold and wet, injuries to the spine, excessive labour, and sexual excesses may possibly act by depressing the general vitality, and so precipitate the disease in a person whose nervous system is already infected.

The disease arises generally between eight and twelve years after syphilitic infection, and is therefore commonest in the middle period of life, between thirty and fifty, and it is noteworthy that tabetics comparatively rarely manifest other signs of constitutional syphilis. It is more frequent in men than women, in about the proportion of ten to one. In the juvenile form, however, which appears in a small proportion of congenital syphilitics during adolescence, the distribution between the sexes is more nearly equal.

Morbid Anatomy. The change constantly found in the spinal cord is a degeneration of the ascending nerve fibres, and sclerosis of neuroglia, in the posterior columns. It is seen as a grey discoloration of the white matter in the fresh specimen, whilst in sections stained by the Weigert-Pal method the pallor of the diseased columns stands out in evident contrast with the deep staining healthy tracts (Plate 54, Figs. 1—3). In ordinary cases it is the fibres entering the lumbo-sacral segments of the cord which are affected, and the degeneration is therefore most evident in the postero-external columns in this region (see Plate 54, Fig. 3), whilst in the cervical enlargement, owing to the displacement inwards of these fibres, it appears in the postero-internal columns. In cases involving the arms the postero-external fibres are degenerated in the cervical region. The association fibres in the posterior columns remain intact, the degenerative process being confined to those fibres which represent the direct continuation upward of the processes of the posterior root ganglia. Under the microscope degeneration and disappearance of the nerve fibres, increase of the glial tissue, which is fibrillated, and thickening of the walls of the arteries are observed. In advanced cases changes may also be detected in the grey matter, such as atrophy and degeneration of nerve cells or fibres in the posterior horns, in Clarke's columns, and even in the anterior cornua. The pia mater is often thickened over the posterior columns, or even over the lateral columns as well, or completely round the cord.

The posterior nerve roots are generally atrophied down to the spinal ganglia, which are mostly healthy, as well as the mixed nerves beyond them. In the optic nerves, in cases alluded to, are found atrophied nerve fibres and overgrowth of neuroglia. Atrophy or degeneration of the nuclei of the third, fourth, fifth, sixth, eighth, and twelfth cranial nerves have in different cases been seen, as well

as of the Gasserian ganglion, but the lesion of reflex iridoplegia in tabes is not certainly known, though it is probably situated in the periaqueductal substance of the mid-brain.

Pathology. Little is absolutely known of the pathology of tabes beyond the fact, which has already been stated, that the disease is primarily a process of destruction of the posterior column nerve fibres due to the activity of the *Treponema pallidum* or its toxins. Since the action in tabes dorsalis and in general paralysis of the insane appears to be directly upon the nervous elements, these two diseases are often spoken of as *parenchymatous syphilis of the nervous system* to distinguish them from those forms of syphilis in which degeneration of nerve cells and fibres is secondary to affections of the meninges and blood vessels.

Owing to the chronic nature of the illness, opportunities for pathological study have been limited mainly to end results, but in early cases the point of initial lesion appears to be the point where the nerve fibres coming from the posterior root ganglion pass through the pia mater to enter the cord.

The delay between the original syphilitic infection and the onset of the disease has been variously explained. The probable sequence of events is as follows and has reference not only to tabes but other forms of neurosyphilis. In the stage of blood stream dissemination spirochaetes find their way to the meninges and give rise to a mild inflammatory reaction. In the great majority of cases this causes no symptoms, but the cerebro-spinal fluid shows an increase of cells and protein, sometimes an abnormality of the gold curve. A positive Wassermann reaction is uncommon. Such changes are to be found in forty to fifty per cent. of all cases of untreated secondary syphilis. It is supposed that in most of these cases, with or without treatment, the meningeal infection dies out, but in a small percentage it continues and there is a chronic but clinically silent meningitis. This may eventually develop in the form of localised gummatous thickening with injury to the brain, cranial nerves or spinal cord, or it may continue as a diffuse leptomeningitis. After a lapse of many years it may then commence to invade the substance of the brain causing a diffuse meningo-encephalitis, which is the basis of general paralysis of the insane. Into the spinal cord it finds entry along the path followed by the afferent fibres as they pierce the pia mater, giving rise to the symptoms of tabes.

Symptoms. As might be expected from its pathological anatomy, tabes is essentially a disease of sensory symptoms, especially in its early stages. The significance of these is readily missed, and yet, seeing that the best we can hope for our treatment is to arrest the progress of the disease, it is most desirable that we should recognise it before gross defects of muscle and joint sensibility have led to a condition of disablement from ataxy. In the early (pre-ataxic) stage the characteristic symptoms are pains in the limbs, cutaneous hyperæsthesia of the trunk or limbs, loss of knee jerk, and loss of pupil light reflex. This stage may last for months or years.

The pains known as *lightning pains* occur in 95 per cent. of the cases; they are severe shooting, stabbing, or darting pains, as a rule in the lower extremities, sometimes in the arms. They come on suddenly, and, it may be, with such severity as to make the patient start up in bed, or cry out. Each pain lasts only for a few seconds, but they generally soon recur and continue thus coming and going in different parts of the limbs for several hours. They may then disappear, and not return till the next day, or till after an interval of days or weeks. They thus present the greatest irregularity both as to recurrence and duration. The patient frequently puts them down to "rheumatism," but if questioned gives a description so graphic as to be quite unmistakable.

The hyperæsthesia of the skin, usually that covering the upper part of the trunk or of the legs, is often noticed early by the patient, who complains that light-stroking contact, for instance putting on and off the underwear, gives rise to a peculiar, unpleasant sensation, which may also be aroused by extremes of

in the stage of arrest or quiescence, both blood and spinal fluid may be normal. Or again a positive blood may be found with a normal fluid.

Prevention. This consists in the prevention of syphilis in the first place, and in the early adoption of vigorous antisyphilitic measures if the disease is contracted.

Treatment. This may be considered under two heads, specific and symptomatic.

Specific. Of recent years it has become a universal practice to employ salvarsan or similar compounds in the treatment of all forms of syphilis, and cases of tabes are usually treated by such means. The principles to be employed are those laid down for the treatment of syphilitic myelitis (*see* p. 666). In the majority of cases symptoms may be alleviated and the course of the disease retarded or prevented by efficient treatment. As in the treatment of syphilitic myelitis, mercury and iodides are also given in tabes.

Symptomatic. For the lightning pains any of the analgesic drugs may be tried, singly or in combination. A powder containing 5 grains each of aspirin, phenacetin and veramon is useful. If other measures fail, opium or its derivatives in some form must be used. Five grains each of aspirin and phenacetin with one-sixth of a grain of heroin hydrochloride makes a useful cachet. Heat also is sometimes of value, and in some instances an attack of lightning pains may be aborted by an analgesic dose taken together with a bath as hot as the patient will stand. Hypodermic injections of morphia should be employed only as a last resort, but are sometimes necessary. As a general rule they should not be given except by doctor or nurse and should be reserved for the severe bouts of pain, for there is a considerable danger of habit formation.

A gastric crisis may sometimes be aborted by giving a bath as hot as the patient can stand it, and then putting him to bed with hot-water bottles and the administration of morphine, $\frac{1}{4}$ grain, hypodermically. At the height of an attack morphia may be necessary to relieve the pain. If the attack is of long duration, rectal feeding is necessary.

In cases in which repeated gastric crises have rendered the patient's life almost intolerable, a surgical procedure which has met with some success is exposure of the spinal cord and division of the antero-lateral ascending tracts in the upper thoracic region.

Attention to the bladder is very necessary, and the catheter should be used if any urine is retained. The expulsive power may be increased by strychnine or incontinence lessened by belladonna.

For the laryngeal crises inhalation of amyl nitrite may give relief.

Much may be done for the ataxia by means of graduated exercises (Fraenkel's exercises). This is essentially a process of re-education by which the patient is taught to compensate for his loss of sense of position by co-ordination of visual impressions with muscular movements. These exercises may be begun in bed, the patient being instructed to practise simple co-ordinated movements such as raising the leg to a certain height and then placing it nicely in contact with an object set up for the purpose. Thence he is led through movements in the sitting and standing postures to those of orderly progression, full use being made throughout of the visual sense. Thus he is taught to stand opposite a wall and raise the foot to touch various marks upon it, while supporting himself with his hands, to advance by placing his feet accurately upon footmarks outlined on the floor, and so on. In this way it is often possible to obtain for a bedridden patient some measure of ambulatory activity.

SUBACUTE COMBINED DEGENERATION

This is a disease *sui generis* characterised by progressive widespread degeneration of the fibres of the posterior and lateral columns of the spinal cord, usually associated with pernicious anæmia, and if untreated leading to a fatal termination.

Ætiology. This disease is most common between the ages of fifty and sixty, the extremes at which the onset has been recorded being twenty-six and seventy. Nothing is known of its true ætiology. Its association in the great majority of cases with pernicious anæmia, and its response to the same treatment, which is of value in that disease, suggests that subacute combined degeneration of the cord is at any rate partly dependent upon a failure of absorption from the diet of some substance essential to the health of the nerve fibres.

Pathology. In the great majority of cases evidence of pernicious anæmia is already present when the symptoms of spinal cord disease first appear. In a few cases, however, the spinal cord symptoms precede those of anæmia.

As in pernicious anæmia, gastric achylia is the rule. Subacute combined degeneration may also occur in association with carcinoma of the stomach, pellagra and ergotism.

Morbid Anatomy. Macroscopic examination shows the spinal cord to be of normal size, in contrast with the condition found in diffuse sclerotic processes. On cross section the degenerated areas in the white matter appear as greyish patches, which in the mid-dorsal region usually form a complete circle around the central grey matter. The degeneration of the longitudinal fibres is the essential feature of the disease. The Weigert-Pal staining method shows, in cases where death has occurred in the earlier stages, that this process commences in the centres of the ascending posterior and descending lateral columns of the lower thoracic region (*see* Plate 55, Fig. 2); thence it extends centrifugally until, in cases where the fatal termination has been delayed, there are no medullated fibres remaining except for the short association fibres surrounding the grey matter.

Similar patches of degeneration occur in the lumbar and cervical enlargements, and the disease process extends longitudinally by coalescence of these patches. The first sign of degeneration is swelling of the myelin sheaths, which then undergo fatty degeneration and break up into droplets which are stained black by the Marchi staining method. With this the axis cylinder breaks up and disappears. The degeneration products are subsequently absorbed, leaving a fine network of neuroglial and connective tissue elements containing empty spaces in place of the destroyed nerve fibres. There are no material changes in the walls of the blood vessels and relatively little overgrowth of neuroglia.

The nerve cells are not affected except as a secondary result of degeneration of their axons. Thus the cells of Clarke's column show vacuolation and chromatolysis consequent upon the degeneration of the spino-cerebellar fibres, and similar changes are found in the Betz cells of the pre-central cortex as a result of destruction of the pyramidal tracts.

In rare cases there are found scattered minute hæmorrhages in the cord, but these probably occur as terminal events, and cannot be considered as a cause of the degeneration of nerve fibres.

Symptoms. The illness is most commonly ushered in by paræsthesiæ of the extremities. These begin with numbness and tingling of the fingers and toes, extending to the hands and feet, and are soon followed by impairment of cutaneous sensibility of the same distribution. The nature of the sensory loss varies; sensibility to pin-prick is generally lost earlier than that to cotton wool, and with extension of the area involved the loss to pain precedes that to touch. In the earlier stages the glove and stocking distribution is retained, but as the anæsthesia progresses from the lower limbs on to the trunk the upper level follows a segmental line. Evidence of affection of the posterior columns is usually found at an early stage of the disease in the form of loss of sensations of position, passive movement and vibration in the extremities, and the knee and ankle jerks are lost. Other subjective sensory phenomena commonly met with are sensations of tightness around the waist and constriction or swelling in the lower limbs.

The signs of pyramidal disease usually follow those already mentioned, and are indicated by the complaint of weakness in the lower limbs and the appearance of

extensor plantar responses. In other cases the lateral columns may be affected first. The patient then complains that his feet feel heavy, and drag as he walks, especially when he is tired. Later the lower limbs become stiff, and the gait is that of a case of spastic paraplegia, though careful examination will probably reveal an ataxic element due to the loss of muscular and joint sensibility. As the posterior columns become more completely involved the spastic picture gives place to that of flaccid paralysis, and the gait resembles that of the tabetic. At this juncture the patient, relieved of his stiffness, may be led to the false hope that he is improving, but with the further development of the ataxy soon becomes bedridden. The paraplegia does not as a rule reach the upper limits of the regions supplied by the cervical enlargement, and even in the later stages of the disease the affection of the upper extremities remains limited to peripheral anæsthesia and weakness.

The sphincters are always affected in the later stages of the disease. At first there may be difficulty in starting the act of micturition, which is followed by loss of control, with the rapid development of complete incontinence of urine and fæces. At this period cystitis is likely to occur, with the sequence of pyelonephritis, leading to a fatal termination, and bedsores inevitably develop.

The mental state toward the end is one of lethargy, drowsiness and complacency, occasionally developing into a state of feeble delirium. The special senses and cranial nerves are not affected. The reflexes are variously affected at different stages of the disease. In the more usual type beginning with sensory disturbance the ankle jerks are lost early, loss of the knee jerks follows, and the plantar responses by this time are usually of the extensor type. In the type which begins with spastic weakness the plantar responses are from the first extensor, the knee and ankle jerks at first exaggerated, subsequently lost. The abdominal reflexes are as a rule retained until a late stage of the disease.

Anæmia is recognisable in about one-half of the cases when first seen. It is of the type met with in pernicious anæmia, see p. 432. The skin often shows a yellowish tint, against which the presence of a bright malar flush may give the face a characteristic aspect.

Although anæmia of this type appears in a great majority of cases before death, there are some which run a course typical of that described above to a fatal termination without ever developing the characteristic blood picture.

Gastric achlorhydria is the rule and may be present without anæmia.

The **Diagnosis** in the early stages is often difficult, but complaint on the part of a person between the ages of fifty and sixty of peripheral paræsthesiæ as described above should always arouse the suspicion of subacute combined degeneration, and lead to a careful investigation of the reflexes, a complete blood examination, and a test meal.

The flaccid type of the disease with absent tendon jerks and peripheral anæsthesia has to be differentiated from *polyneuritis*. The calves may be tender to pressure in both diseases. The main points of clinical value in distinguishing the two are the presence in the history of subacute combined degeneration of girdle sensations and defective sphincter control and on examination a predominant affection of deep rather than cutaneous sensibility with extensor plantar responses.

This type of the disease also has to be distinguished from tabes in which the pyramidal tracts may be occasionally involved with extensor plantar responses. The history of the illness, together with the frequent occurrence in tabes of pupillary abnormalities, are points of importance in this connection, and the examination of blood and spinal fluid will settle the question.

The spastic type must be distinguished from *disseminated sclerosis*, in which the presence of nystagmus and intention tremor and a history of transient disturbances of sensation, power, or vision are commonly present.

The manner of the onset is sufficient to distinguish the disease from acute

myelitis or a spinal tumour. The only other illness of note in which combined posterior and lateral column degeneration occurs is *Friedreich's disease*, from which subacute combined degeneration is easily differentiated by the age incidence and other signs.

The absence of free hydrochloric acid in the gastric juice and the macrocytic anæmia, which are characteristic of most cases of subacute combined degeneration, furnish positive evidence of a kind which usually suffices to decide the diagnosis in a doubtful case.

Prognosis. Until recently the prognosis was considered to be almost uniformly bad, the tendency being towards a fatal issue from cystitis or bedsores within two or three years of the onset, although in rare cases remissions might occur. With the advent of the liver treatment of pernicious anæmia the outlook in subacute combined degeneration became more hopeful, and it is now apparent that in cases of pernicious anæmia in which symptoms of spinal cord disease have not yet appeared they may be prevented; that when the spinal cord degeneration has already commenced its progress may be arrested; and that in many cases the symptoms and signs of subacute combined degeneration may be considerably improved. These results, however, are only to be obtained by means of adequate and persistent treatment.

Treatment. The treatment is that for pernicious anæmia and has already been described. For the treatment of subacute combined degeneration it is essential that liver extract, desiccated stomach, and iron should be given in doses sufficient to achieve and maintain a normal blood picture, and that over and above this an extra margin of maintenance dosage be allowed for the treatment of the spinal cord disease. In cases in which the disease has become arrested with treatment, but with posterior column damage, Fraenkel's exercises as recommended for tabes may be of great help.

FRIEDREICH'S ATAXIA

The characteristic feature of this disease is its congenital tendency and its appearance in several members of the same family. Thus a man may transmit it to his children, or it may appear in two or more brothers and sisters without the parents being affected. It affects males only a little more often than females, though males may be especially affected in one family, females in another; and it is generally first noticed at an early age, either about the seventh or eighth year, or at puberty. Non-familial cases also occur.

Pathological Anatomy. Degeneration is found in the posterior columns in the spino-cerebellar tracts and in the pyramidal tracts (Plate 55, Fig. 3). Both sides of the cord are affected symmetrically, and the degeneration is most marked at the mid-thoracic level. The cells and fibre network of Clarke's column show changes in association with the degeneration of the spino-cerebellar fibres. The cerebellum as a rule shows no pathological changes.

The cause of the disease seems to be a congenital want of vitality in the neuron systems or tracts involved.

Symptoms. The onset is as a rule gradual, and the disease is first manifested in a certain clumsiness of the gait and a tendency for the child to fall about when at play or when performing actions requiring a nice balance. These symptoms depend upon inco-ordination, which conforms to the cerebellar type and may be demonstrated by means of the various tests already described (finger-nose-finger and heel-knee tests, diadochokinesis). The arms are affected as a rule rather later than the legs. While at rest the patient may show irregular jerky movements of the limbs somewhat resembling those of chorea, and in particular there is to be noticed a nodding tremor of the head.

The inco-ordination is not confined to the limbs, but also affects the speech musculature, so that the utterance is hesitating and explosive. Nystagmus is usually present, but is not a prominent feature of the illness. The knee and

ankle jerks are lost comparatively early by reason of involvement of the posterior columns, and the plantar reflexes are extensor as soon as the pyramidal tracts are affected.

A peculiar feature of the disease is the almost constant presence of certain skeletal deformities. Of these the most characteristic is *pes cavus*, a condition in which the arch of the foot is greatly exaggerated and the toes are hyper-extended at the metatarso-phalangeal, flexed at the interphalangeal, joints. The other is *scoliosis*, or lateral curvature of the spine in the dorsal region, with which is usually associated some degree of *kyphosis* or forward curvature. The causes of these deformities are imperfectly understood.

Sensibility is not as a rule affected to any important extent, but in some cases diminution of both the superficial and deep forms of sensation may be discovered on careful examination. The sphincters are not affected. In patients who show signs of the disease before the age of puberty physical development is usually retarded, and the mentality also remains somewhat childish. The disease is slowly progressive over a number of years, but not directly fatal.

Diagnosis. This has to be made from *juvenile tabes*, in which the common occurrence of Argyll-Robertson pupils, optic atrophy and associated signs of congenital syphilis, together with the Wassermann reaction in blood and spinal fluid, serve to make the differential diagnosis certain. Friedreich's ataxy may also resemble *disseminated sclerosis*, which, however, is seldom fully developed at such an early age, and in which the tendon jerks are exaggerated, not lost. In *cerebellar tumour* the signs of increased intracranial pressure are usually evident, but apart from this there are cases of *hereditary cerebellar ataxy* which are distinguished with some difficulty from Friedreich's disease.

Prognosis. This is unfavourable. The patient tends eventually to become bedridden after a period of ten or fifteen years, and as a rule dies comparatively young of some intercurrent affection.

Treatment is of little avail, but some improvement may be effected by means of systematic and continued training after the manner of the exercises employed for the treatment of *tabes dorsalis*.

PERONEAL MUSCULAR ATROPHY

(Charcot-Marie-Tooth Disease)

The main features of this disease are the distribution of the muscular wasting, its slow progress, and the frequency with which a hereditary tendency is manifested by cases occurring in blood relations. As a rule it is transmitted directly to succeeding generations by persons themselves affected. Although isolated cases are reported, careful search often reveals unmistakable signs of the disease in supposedly unaffected members of the family.

Pathological Anatomy. Degeneration is found in the anterior horn cells corresponding to the wasted muscles, in the peripheral nerves, and in the posterior columns (3).

Symptoms. These usually commence in childhood, but in exceptional cases may first appear in middle life. The onset is gradual with wasting and weakness of the small muscles of the feet, and of the anterior tibial group, especially the peronei. This results in characteristic deformity and difficulty in walking. The toes become curled up owing to over-extension at the metatarso-phalangeal and over-flexion at the inter-phalangeal joints; the plantar arch is raised and shortened, producing a *pes cavus*, and the foot is dropped at the ankle joint and inverted. The patient, therefore, has difficulty in clearing his foot from the ground, and is apt to trip over his toes, especially when hurrying.

As the disease progresses the small muscles of the hands are often next affected. The progress of the disease is often extremely slow and may not extend further than this. When it does so the wasting gradually extends up the lower limbs in a

somewhat characteristic fashion, affecting first the calves, and then the lower parts of the thighs. Fibrillary twitchings may occur in the wasting muscles, and the electrical reactions in most cases show R.D.

There may be complaint of numbness and tingling in the feet at the commencement of the disease, but there is no objective sensory disturbance.

Loss of tendon jerks as a rule precedes muscular wasting, so that all the tendon jerks of upper and lower limbs may be abolished at a stage when wasting is confined to the feet. There are, however, exceptions to this rule, and in practice it is found that each family group of these patients, though remaining true to its own type, shows variations from others. The mental condition, special senses, cranial nerves and sphincters are unaffected.

Diagnosis. The differential diagnosis has to be made from Friedreich's disease. In both there are *pes cavus* and absent tendon jerks with a family history of the disease, but in Friedreich's ataxia there are signs of damage to the cerebellar and pyramidal fibres. The absence of such signs in peroneal muscular atrophy, together with the wasting of the anterior tibial group of muscles, as a rule makes the distinction easy.

The distal type of progressive muscular dystrophy is not so easily distinguished. The points in favour of peroneal atrophy are the occurrence of fibrillary twitchings, the early loss of tendon jerks, and reaction of degeneration in the affected muscles.

Prognosis. The course of the disease is so slow that the disability in many cases is slight, and the patient may continue to get about with the aid of special boots and orthopædic apparatus. In some cases, after a period of five to seven years, the affection seems to become spontaneously arrested.

Treatment. Special boots, night splints, and in some cases walking apparatus, are needed to correct deformities. Massage and passive movements are also useful.

MOTOR NEURON DISEASE

This title has been taken to include the diseases formerly described in this volume under the separate headings of progressive muscular atrophy, amyotrophic lateral sclerosis, progressive bulbar paralysis and primary lateral sclerosis. The pathological process, so far as is known, is the same in all these maladies, being characterised by a primary degeneration of the upper or lower motor neurons, or most commonly of both together. The exact clinical picture varies with the preponderance of upper or lower neuron involvement and the level of the cerebro-spinal axis chiefly affected.

Ætiology. Our knowledge of the origin of this disease is very incomplete. It is a malady of middle and late life, and it is more common in males than in females. A small proportion of cases appear to be due to syphilis, as proved by a positive Wassermann reaction in blood or spinal fluid, but in the great majority no cause whatever can be found for the degeneration.

Morbid Anatomy. Macroscopic changes are inconspicuous. The spinal cord may appear shrunken in the cervical and lumbar enlargements and the pre-central convolutions of the brain show similar atrophy. Under the microscope there is what seems to be a primary degeneration of the pyramidal fibres in the spinal cord frequently extending upwards to the internal capsule and cerebral cortex. The fibres of the antero-lateral tracts in the cord also appear to be thinned, so that in a Weigert-Pal stained section (*see* Plate 55, Fig. 1) the healthy posterior and postero-lateral columns stand out in marked contrast to the affected areas. Sections stained by the Nissl method show a great diminution in the number of motor cells in the anterior cornua. Of those that remain most are shrunken and degenerate. Similar changes may be seen in the nuclei of the brain-stem, especially the twelfth and the motor nuclei of the vagus, and in the Betz cells of the motor cortex.

The affected muscles show degeneration and atrophy with proliferation of the sarcolemma nuclei, and some replacement fibrosis, but no deposition of fat such as is seen in the myopathies.

Symptoms. The clinical picture varies with the situation of the cells and fibres chiefly affected. In the commonest type (*progressive muscular atrophy*) weakness and wasting of the upper limbs is the initial symptom. This begins usually in the small muscles of the hands, both being affected together or one after the other. The thenar eminences are flattened, the hollow of the palm is accentuated and the line of the ulnar border of the hand loses its contour from wasting of the hypothenar muscles. On the dorsal surface hollows or "gutters" appear between the metacarpal bones from disappearance of the dorsal interossei, the hollow between the index finger and thumb being conspicuous. If the muscles of the forearm retain their power the fingers tend to fall into the "claw" position, extended at the metacarpo-phalangeal and flexed at the terminal joints from unopposed action of the long extensors and flexors. The thumb, on account of weakness in its intrinsic muscles, falls back into line with the fingers with pad facing forwards—the ape hand. There is no particular order of spread to the other muscles of the upper limbs, but those of forearm and shoulder are often affected, while the biceps and triceps still escape. The muscles of the neck, trunk and lower limbs are subsequently affected. In the latter the thighs are usually involved first. Not uncommonly, the disease spreads to the bulbar nuclei. In other cases the disease begins in this part (*progressive bulbar paralysis*), and the patient presents himself on account of dysarthria, dysphagia, or more rarely hoarseness. The tongue is first and chiefly affected and the fibrillary twitching, which is a characteristic but inconstant accompaniment of the wasting in the other muscles affected, is hardly ever absent in this organ. The muscular atrophy also betrays itself early by the appearance of creases and hollows in the enveloping mucous membrane. Together with the tongue the muscles of the lips are usually involved, increasing the difficulty of articulation, so that often before there is any striking abnormality in the outward appearance, speech becomes thick and unintelligible. Involvement of the palate and pharynx lead to dysphagia, and of the vocal cords to hoarseness. The masticatory and upper facial muscles are not often involved, and the ocular muscles hardly ever. In rare instances the disease may commence in the lumbar enlargement with weakness and atrophy of the lower limbs, usually first apparent in the thighs.

As a rule, the wasting and weakness advance *pari passu*, but there are cases, especially when the disease is rapidly progressive, in which muscles of a considerable bulk are found almost powerless. Together with the atrophic palsy there is nearly always some evidence of upper neuron involvement. Despite the atrophy, the tendon reflexes are usually brisk or even exaggerated in the early stages, only disappearing with the muscles themselves. An exaggerated jaw jerk is characteristic of the cases with bulbar involvement. The plantar responses sooner or later take the extensor form.

Sometimes, but rarely, the upper neuron involvement precedes or overshadows the other, and the disease is characterised by spastic weakness, especially of the lower limbs. This may be accompanied by atrophic weakness of the hands or bulbar muscles (*amyotrophic lateral sclerosis*), or the degeneration may remain confined to the pyramidal fibres (*primary lateral sclerosis*).

There is no objective impairment of sensory function, but in some cases the muscular atrophy may be preceded by complaint of shooting pains and tingling in the limbs. The fibrillary twitching, if severe, may be a source of discomfort. Sphincter control remains normal unless the pyramidal fibres are severely involved. The mental condition is usually unaffected, but in cases showing much involvement of the pyramidal tracts above the bulbar level there is frequently some loss of control over the expression of the emotions, so that the patient laughs, or more usually weeps, with unusual readiness.

Prognosis. The course of the illness is gradually progressive. The rate of progress is variable. At the extremes death may occur within a year of the onset, or the patient may be living at the end of fifteen years. The rate of progress in the individual case tends to remain steady, so that some idea of the prognosis may be gained after a period of observation. Cases with early involvement of the bulbar or respiratory muscles are most likely to run a short course. Those in which the wasting remains confined to hands and forearms (*progressive muscular atrophy*) may progress very slowly, and the same applies to those in which the pyramidal tracts only are affected. Death is usually due to intercurrent infection of the respiratory tract. Bulbar involvement opens the way to an aspiration broncho-pneumonia.

Diagnosis. The form characterised by early wasting of the hands (*progressive muscular atrophy*) has to be distinguished from the effects of any focal lesion in the cervical enlargement of the cord, such as tumour or chronic meningitis or pressure from diseased bone. The presence of sensory loss below the segmental level of the lesion, together with alterations in the contents or pressure of the spinal fluid, will usually serve to distinguish these. The distinction from syringomyelia may be difficult on account of the tendency in both maladies for bulbar and hand muscles to be involved simultaneously with the pyramidal tracts. A careful sensory examination may be necessary to settle the doubt.

Lead palsy may be distinguished by the characteristic distribution of the paralysis and other evidence of lead poisoning.

Cervical ribs cause atrophy of the hand muscles and may be bilateral, but in these cases the wasting is strictly limited to the hands. An X-ray will help to settle the question. The wasting of an *ulnar or median neuritis* is accompanied by its appropriate sensory loss. The hands may be involved in *peroneal muscular atrophy*, but after the feet.

The cases with bulbar onset (*progressive bulbar paralysis*) have to be distinguished from the pseudo-bulbar paralysis (see p. 702) due to vascular lesions. The absence of wasting and the history of a sudden onset in the latter are the distinctive features.

The cases which begin with spastic weakness of the lower limbs have to be diagnosed from the various transverse lesions of the cord, which may produce a similar picture, such as disseminated sclerosis, spinal tumour, spinal syphilitic meningitis, and from subacute combined degeneration. It may be possible to arrive at a conclusion only after a considerable period of observation.

Treatment. Except for the rare cases in which a syphilitic origin can be proved, there is no treatment which has any power to arrest the progress of the disease. An examination of the blood and spinal fluid should be made in every case, and if either shows a positive Wassermann reaction a course of anti-syphilitic treatment should be instituted. Treatment otherwise is palliative. A good nutritious diet, exercise without strain, and avoidance of mental fatigue are desirable. In the way of local treatment massage helps to preserve the muscles by maintaining the circulation. The function of the affected muscles is improved by warmth, so that radiant heat of any kind may be helpful.

Although public faith in the efficacy of electrical stimulation may force the hand of the physician, its effect, if any, is probably harmful.

LANDRY'S PARALYSIS

In 1859 Landry described cases of paralysis commencing in the lower extremities, rapidly ascending, and soon fatal, for which no pathological cause could be found on examination. Cases of the kind still occur in which the coarser lesions of myelitis and softening are entirely absent.

Ætiology. The disease affects males more than females, and is most frequent between the ages of twenty and forty. It has occurred after exposure to cold, in convalescence from acute diseases, and in patients addicted to

alcohol; and a few cases have been recorded after cystitis or other forms of urinary sepsis. In the majority of instances, however, no adequate predisposing causes are to be found.

Pathology. In some rapidly fatal cases the spinal cord, nerves, and muscles have been found completely free from disease. In others there have been varying degrees of degenerative change (chromatolysis and displacement of the nucleus) in the cells of the spinal cord, especially those of the anterior cornua, and of Clarke's columns, with more or less vascular engorgement, but no hæmorrhage or perivascular infiltration of leucocytes. There may be changes in the myelin of the anterior roots and of the white columns of the cord, but none in the peripheral nerves. Occasionally, when the fatal termination has been delayed, the Marchi method reveals the presence of degenerative changes in the peripheral nerves, which are probably secondary to those in the anterior horn cells. It is clear from the above account that the histological picture in Landry's paralysis is quite distinct from that of an ascending myelitis, peripheral neuritis or anterior poliomyelitis. Micro-organisms, but not always the same, have been found by different observers in the nerves, spinal cord, meninges, and blood.

Symptoms. In some cases there are premonitory symptoms, such as malaise, pain in the head and back, and numbness and tingling, but usually the disease begins with weakness in the legs, often one before the other. This soon increases to definite paralysis, and invades successively, and within a few days (or in acute cases in a few hours), the thighs, trunk, abdomen and arms; and these, like the legs, are not always affected simultaneously. The diaphragm and the muscles of the neck, of the palate, and those subserving articulation are subsequently paralysed. Very rarely other cranial nerves are affected; thus diplopia, paralysis of accommodation, dilatation of one pupil, and facial paralysis have been noticed. As a rule cutaneous sensibility is normal, though there may be some loss to light touch in the peripheral areas of the extremities. The sensations of passive movement and position are unaffected. In rapidly fatal cases the muscles have not wasted, and the electrical reactions have appeared to be normal; but in some cases of longer duration both atrophy of muscles and modifications in electrical properties have been observed. Control over the urinary and rectal sphincters is not lost, and there is no tendency to bedsores; the cerebral functions are perfect, and there is no fear except in a few cases at the very onset. The tendon jerks and skin reflexes are lost as the corresponding muscles become paralysed.

Diagnosis. This has to be made from acute ascending *myelitis*, from infective *poliomyelitis*, and from *multiple neuritis*. The first of these is distinguished by the pronounced loss of sensation, and the early implication of the bladder. In *poliomyelitis* there is more general disturbance—fever, headache, pains, perhaps convulsions—and the paralysis is rarely quite uniform or symmetrical. In *multiple neuritis* symptoms come on gradually, paralysis appears in the peripheral parts of the arms and legs almost at the same time, and the nerves and muscles are tender.

The mortality is high—e.g. 58 per cent. in cases collected by Ross; these, however, probably included some cases of peripheral neuritis. The duration of the disease is from two days to two or three weeks in fatal cases, and death occurs mostly from paralysis of the diaphragm and intercostal muscles. On the other hand, the symptoms persist from two to six or seven months in cases which recover; but recovery is generally complete.

Treatment. This may be the same as that of multiple neuritis or acute myelitis.

SENILE PARAPLEGIA

In people of advanced age the lower limbs may become weak and unsteady, and walking slow and difficult, without any of the physical signs characteristic of

the diseases of the spinal cord which have already been described. The term senile paraplegia, sometimes applied to such cases, has probably been used to cover a number of different conditions in which such symptoms may occur. In the majority the lesion is cerebral rather than spinal, being due to arterial thickening with consequent softening of the brain substance. Pathological examination shows a tendency for such areas of cerebral softening to be symmetrical, with frequent involvement of the basal ganglia, although other parts may be involved. A careful neurological examination will reveal in these cases some defect of function of a Parkinsonian, pyramidal or cerebellar type, which, though it chiefly affects the lower limbs, also involves the arms and trunk. The condition is slowly progressive. Adequate rest, with massage, passive movements and educational exercises, may be of some help.

MENINGITIS

In the cerebral as in the spinal meninges, we have to distinguish an inflammation of the dura mater, or *pachymeningitis*, and inflammation of the arachnoid and pia mater, or *leptomeningitis*.

The pia mater appears to be much more subject than the dura mater to the influence of micro-organisms, and to these bodies nearly all forms of leptomeningitis can be traced.

The organisms most often concerned are—

1. The *pyogenic organisms* (streptococci, staphylococci) which may invade the meninges in pyæmia and septicæmia, after injury to, and operations on, the cranial bones, and in diseases of the ear, nose, and frontal sinuses; these cause a *suppurative meningitis*.

2. *Tubercle bacilli*, secondary to a tuberculous focus, either in the brain itself or in some other part of the body.

3. The *pneumococcus*, often in association with pneumonia, as part of malignant endocarditis, or as a primary affection.

4. The *meningococcus*, or *Diplococcus intracellularis* of Weichselbaum, which causes cerebro-spinal fever, or epidemic cerebro-spinal meningitis, including its posterior basal variety.

5. *Syphilis* is a frequent cause of meningitis, which is, however, generally subacute or chronic in its course.

6. The bacilli of *influenza*, *typhoid fever*, the *gonococcus*, the *Bacillus coli communis*, and other organisms have been found in some cases.

The results of bacterial invasion are seen in the effusion of lymph or of pus on the surface of the brain, often with an increase in quantity of the cerebro-spinal fluid.

There is a general resemblance to what has already been described under the head of cerebro-spinal fever and tuberculous meningitis.

SUPPURATIVE MENINGITIS

Ætiology. If we exclude cases of cerebro-spinal fever, a purulent meningitis is in the majority of cases the result of invasion by the pyogenic or septic organisms, and arises in circumstances similar to those which lead to abscess of the brain; that is, its common cause is a focus of disease in the immediate neighbourhood. Thus it may follow injuries to the head, or be set up by extension of inflammation in neighbouring parts, such as otitis media, mastoid suppuration, disease of the nasal cavities, syphilitic caries or necrosis of the skull, suppurative phlebitis, or abscess of the brain. But it occurs also as a complication in some general diseases of an acute, febrile, or infective nature—pyæmia, septicæmia, pneumonia, and malignant endocarditis.

Pathology. The inflammation chiefly affects the pia mater and arachnoid (*leptomeningitis*). When it has spread from a diseased bone of the skull, the dura

mater itself may show localised inflammation, but the extension of the disease over the brain is by means of the other membranes. Commonly the convex surface of the brain presents a more or less extensive layer of bright yellow or green pus, which may be on both sides, or confined to one side, the side of the lesion in secondary cases. The pus frequently follows the course of the larger vessels, and dips down with the pia mater into the sulci. Though mostly affecting the upper surface of the hemispheres (meningitis of the convexity), it usually extends to the base, and into the spinal canal. The brain tissue beneath it is commonly softened, and may present ecchymoses or minute abscesses.

Symptoms. While there is a general resemblance to the symptoms of tuberculous meningitis, the course of acute meningitis is usually much more rapid, and there is much diversity as to the prominence of particular symptoms. Where meningitis supervenes upon other acute illnesses, its features may be more or less masked. In cases without apparent cause, and in cases caused by chronic inflammatory lesions, like otitis, the symptoms often commence acutely with chill or rigor, and acute pain in the head. This is generally very severe and constant and aggravated from time to time. The patient becomes feverish, shuns light and noises, and may lie curled up in bed, resenting interference, as in the tuberculous cases. Vomiting often occurs at the commencement. There may be rigidity of the muscles at the back of the neck, and the head is drawn back. The pupils are often contracted. Kernig's sign is usually present. Convulsions also may occur quite early, and may be followed by active delirium, or by drowsiness accompanied by delirium; and in later stages there is often paralysis, with repeated attacks of convulsions, generally bilateral. The paralysis is very variable, corresponding to the situation of the effusion; from its frequent occurrence at the vertex it less often affects the cranial nerves than does tuberculous meningitis, though there may be squint; but an arm or leg is often paralysed, or there may be complete hemiplegia. Sometimes there is rigidity of the paralysed limbs, or of their fellows. The pupils become dilated, and the ophthalmoscope sometimes reveals optic neuritis, which may develop rapidly under observation. The temperature is high, varying from 102° to 104° , the pulse is mostly rapid, respiration is sighing, irregular, or of Cheyne-Stokes type, and in some cases the abdomen is retracted. The drowsiness passes into deep coma, and, finally, the evacuations are passed involuntarily, the breathing and circulation fail, mucus accumulates in the chest, and death terminates the scene. The disease is often fatal within two or three days of the first symptom, and sometimes even less. The cerebro-spinal fluid by the time that clinical suspicions have led to lumbar puncture is usually hazy or turbid, but in the early stages of an acute meningitis the fluid may be clear to the naked eye. On examination it contains an increase of cells, of which the large majority are polymorphs. The protein also is increased and the chlorides diminished as a rule in proportion to the cell increase. Microscopic examination and cultivation will often reveal the causal organism.

Diagnosis. Where there is a primary source, such as otitis media, the diagnosis is generally easy. In the other cases the initial symptoms may resemble those of any acute infection. Headache, however, is usually a prominent symptom, or when the spinal cord is first involved, pain in the back. The routine employment in all cases of obscure pyrexia of the tests for *neck stiffness* and *Kernig's sign* will as a rule ensure an early diagnosis. In some cases, however, in which the anterior parts of the cerebral meninges are chiefly affected, as for instance in a meningitis secondary to frontal sinusitis, neck stiffness may be late in developing, severe and persistent headache being the prominent feature. Lumbar puncture is the final test, and by this means the diagnosis of meningitis may usually be made at the bedside from naked eye inspection of the fluid, which is hazy or turbid. The nature of the meningitis can be determined only by bacteriological examination.

Prognosis. The majority of cases of suppurative meningitis are fatal, but a fair proportion of the milder cases, such as may be seen complicating otitis media, recover. The most important criterion in these cases appears to be the presence or absence of bacteria in the spinal fluid. If the causal organism can be seen in direct smears, or grown easily on culture, the prognosis is almost invariably bad.

Treatment. Where a primary focus, such as mastoiditis or frontal sinusitis, is present this should be dealt with surgically as soon as possible. Lumbar puncture should be performed daily, and the spinal fluid, which is usually under considerable pressure, should be allowed to drain until the rate of flow appears normal. This procedure is frequently successful in relieving headache and neck stiffness, and in the milder cases already referred to may lead to complete recovery, the fluid gradually becoming normal. Morphia is often necessary to relieve pain and allay irritability. In syphilitic cases treatment with neo-salvarsan should be instituted at once. If the streptococcus be identified as the causal agent anti-streptococcal serum should be given subcutaneously, or intravenously.

SYPHILITIC MENINGITIS

The syphilitic virus may in rare instances give rise to the symptoms of an acute leptomeningitis (*see* p. 690). These cases occur shortly after the primary infection during the stages of general dissemination of the spirochætes. Much more common than this is a chronic inflammatory process of syphilitic origin occurring at a later period, from one to five years or even later, after the initial infection which affects both pia-arachnoid and dural membranes in a widespread manner, and gives rise to symptoms both by strangulation of the cranial nerve roots and by causing an increase of intracranial pressure.

Morbid Anatomy. The appearances are very similar to those already described in connection with syphilitic meningomyelitis (*q.v.*). As a rule pia-arachnoid and dural membranes are affected together and become welded into a dense fibrous mass, which may be as much as $\frac{1}{2}$ inch in thickness and envelop the whole of one or both hemispheres. At the base of the brain the leptomeninges alone may be affected, but are usually adherent to the dura. The interpeduncular space is a common situation for this form of meningitis, from which may result compression of the upper cranial nerves, particularly the third and sixth pairs, and also interference with the arterial branches of the circle of Willis. As in the case of syphilitic involvement of the spinal meninges, there is always a certain amount of vascular disease accompanying the meningitis. This takes the form of endarteritis and perivascular sheathing with lymphocytes. With this is associated some degeneration of the underlying nervous substance itself. Thrombotic occlusion of the narrowed vessels may lead to the additional feature of patches of cerebral softening.

Symptoms. The symptoms of the rare form of acute syphilitic meningitis occurring in the early stages of the disease are similar to those met with in other acute inflammatory affections of the leptomeninges, and have already been described.

The main clinical features of the chronic variety are intense headaches, together with vomiting and other signs of increased intracranial pressure, and multiple paralyses of the cranial nerves. In the early stages the symptoms are very frequently intermittent. Thus the cranial nerve palsies—and it is the third and sixth nerves which are most often affected—are commonly transient; and the headache may come on in paroxysmal attacks, lasting a few hours or a few days, which are followed by relatively long intervals of quiescence. Papilloedema may be present, or a gummatous mass pressing upon the optic chiasma may lead to optic atrophy with alterations in the visual fields similar to those met with in pituitary tumour.

The cranial nerves are picked out in a random manner indicative of the wide-

spread distribution of the inflammatory process. Localised patches of thickening upon the surface of the hemispheres may give rise to attacks of Jacksonian epilepsy (*q.v.*), which may be followed in turn by paralyses of monoplegic or hemiplegic distribution. As the disease progresses the headaches become more continuous, and the cranial nerve palsies more constant.

Mental deterioration is a frequent symptom resulting from the combination of increased intracranial pressure with syphilitic disease of the blood vessels. The syphilitic endarteritis also may lead to additional symptoms of cerebral thrombosis with sudden onset of paralysis of one or more limbs.

Diagnosis. The chronic form of syphilitic meningitis has to be distinguished from other conditions which give rise to signs of increased intracranial pressure with paralysis of the cranial nerves. Of these the most important is cerebral tumour. Points in favour of a syphilitic origin are a relapsing tendency and scattered cranial nerve palsies. A strongly positive Wassermann in the blood and cerebro-spinal fluid is the rule in cerebral syphilitic meningitis, but occasionally the reaction may be negative in one and positive in the other. It follows that an examination of both is necessary to exclude syphilis in a doubtful case. There is frequently an excess of cells and protein in the cerebro-spinal fluid. In cases of cerebral tumour the Wassermann reaction is negative in both blood and fluid.

Some cases of syphilitic meningitis with mental deterioration, headaches, and epileptic attacks may closely simulate general paralysis of the insane, especially if the Wassermann reaction is positive in the cerebro-spinal fluid. The diagnosis in such an instance may usually be arrived at by observing the results of anti-syphilitic treatment. When the disease is mainly confined to the meninges the symptoms as a rule disappear, and the Wassermann reaction often becomes negative under treatment, whereas neither of these results is obtained in general paralysis.

The **Prognosis** is good in cases which are diagnosed and effectively treated in the early stages, but, as in the case of syphilitic disease elsewhere in the body, there is a tendency to relapse, and it is well, therefore, for the patient to submit to a short course of treatment annually as a preventive measure against recurrence.

Treatment. This is the same as for syphilis elsewhere, with the provision, however, that it is best not to commence with intravenous injections of arsenical compounds, such treatment being liable in some cases to provoke an initial reaction in the inflammatory tissue with increased symptoms of intracranial tension. It is, therefore, wise to begin with potassium iodide, which should be given in large doses (45 to 90 grains daily) for the first fortnight, after which treatment should be continued on the lines already indicated (*see p. 666*).

PACHYMENINGITIS INTERNA HÆMORRHAGICA

This is a condition in which a mass of blood and partially organised blood clot is found upon the surface of the brain between the dura and the arachnoid membrane. This is usually surrounded by adhesions by which it is encapsuled.

Ætiology. The condition is found most commonly in association with chronic alcoholism and chronic insanity and in old persons. Two views have been put forward as to its causation, (1) that the initial process is inflammatory (of toxic origin), with subsequent extravasation of blood from engorged capillaries; (2) that the effusion of blood is of traumatic origin and that the subsequent encystment results from the reaction of the meninges to the mass of blood clot. In favour of the second explanation Trotter has put forward the arguments that the condition in no way differs from that known to occur as a delayed result of head injury, and that the insane person or alcoholic is quite likely to sustain a head injury and subsequently forget its occurrence. According to Trotter, then, the effusion is due to oozing from the veins passing from the surface of the brain to the longi-

tudinal sinus, and the laceration of these vessels is due to an unrecognised head injury. Sudden displacement of the brain, especially in a forward or backward direction, may be supposed quite readily to cause such laceration, and may possibly result from a trivial blow. If this view is correct the condition is identical with that described in surgical text-books as *chronic subdural hæmatoma*.

Morbid Anatomy. The inner surface of the dura mater is covered with one or more layers of membrane, soft and friable when recent, tougher and more fibrous when old, in colour brownish red, brown, brownish grey, yellow, or even white, and often presenting punctiform ecchymoses; while between the layers may be considerable quantities of blood clot more or less altered by age, or collections of serum containing cholesterin crystals. The deposits are usually situate over the parietal region, near the middle line, and are bilateral in about half the cases. They may be mere membranes, or 2 or 3 mm. in thickness, and if much blood is extravasated, the surface of the brain is depressed. Micro-organisms have been looked for but have not been found.

The **Symptoms** are very variable. Often the condition has been found *post-mortem* without any symptoms which would be explained by it; sometimes, on the other hand, it is fatal as the result of a large hæmorrhage between the membranous layers, which compresses the brain. The symptoms are those of increased intracranial pressure—headache, drowsiness, papilloedema and mental deterioration, and those due to pressure upon the cerebral hemisphere—unilateral weakness with spasticity, increased tendon jerks and an extensor plantar response. If the effusion be left-sided aphasia may be a prominent symptom, and in the bilateral cases there may be a progressive double hemiplegia. It is somewhat characteristic of the condition that the symptoms both of pressure and paralysis vary from day to day. The patient may lapse into coma for a day or two and revive, and the process may be repeated, and the parietic signs also may fluctuate from day to day. Twitching of the limbs may occur but true epileptiform convulsions are uncommon. The cerebro-spinal fluid pressure may be increased as in cerebral tumour, but is sometimes normal. Its constituents usually show no abnormality but may include altered blood pigment.

Diagnosis. This has to be made from cerebral thrombosis and from causes of increased intracranial pressure, such as tumour and syphilis. A history of symptoms appearing gradually after a head injury is of the greatest value, but the latent interval may be one of weeks or even two or three months, the injury may have been a slight one, and in the alcoholic or senile patient it may have been forgotten. The progress of symptoms is, as a rule, much slower and more uneven than that of a cerebral thrombosis. Syphilis may need to be excluded by examination of blood and cerebro-spinal fluid. The distinction from cerebral tumour is more difficult, and is often achieved only with the aid of an exploratory craniotomy. Indeed, in many cases the unsuspected hæmatoma has been exposed by an operation designed to discover a cerebral tumour.

Treatment. If the diagnosis can be made correctly the proper treatment is surgical decompression with evacuation of the mass.

SPINAL MENINGITIS

The membranes of the spinal cord may be involved, together with those enveloping the brain, in acute meningitis of any cause. The pathological appearances and symptoms of this condition are described elsewhere in this volume (*vide* Meningitis). The inflammatory changes due to syphilis (p. 108) and tubercle (p. 88) have also been referred to.

There is one other condition which deserves separate mention. *Meningitis serosa circumscripta* is the name given to a condition in which over a circumscribed area adhesions are formed between the cord, the leptomeninges, and the dura. Cerebro-spinal fluid may be enclosed within the meshes of the

newly formed tissue, so that a cyst-like appearance is produced. The ætiology in some cases is obscure, but in a considerable number the origin, as it appears from the history, is traumatic, although the pathology of the condition has not been satisfactorily explained. The symptoms, which are due to compression of nerve roots and spinal cord, may follow upon those of a definite traumatic lesion of the cord or an injury to the back without spinal symptoms at the time, and develop after a latent interval of weeks or months. Their nature depends upon the level affected and the degree to which the roots or the spinal cord itself are relatively involved. Thus the early symptoms may consist of root pains and muscular twitchings, followed by sensory loss and wasting of segmental distribution and signs of spinal cord compression only as a late development, or the clinical picture may be that of a gradually progressive transverse lesion of the cord from the first without root involvement. The diagnosis has to be made from other transverse lesions such as may be caused by tumour, syphilis or disseminated sclerosis. X-ray evidence of former injury to the vertebral column may be a valuable point when there is a doubtful history of trauma. An exploratory laminectomy may be necessary to settle the diagnosis. The symptoms may be relieved by incision of the membranes with release of the localised collection of fluid, but the condition shows a tendency to recur.

DISEASES OF THE BRAIN

CEREBRAL HÆMORRHAGE

In dealing with diseases of the brain prominence must be given to vascular lesions, which are responsible for the majority of cases of cerebral paralysis. Rupture of the vessels, with escape of blood (*hæmorrhage*) into the brain, and obstruction of the arteries by *embolism* and by *thrombosis*, are the forms of acute vascular lesion which have to be considered.

Ætiology. Cerebral hæmorrhage occurs more frequently in men than in women, and more in advanced life than in youth. The cause, as a rule, is arterial disease, almost always in association with a high blood pressure. Thus it is a common event in diffuse hyperplastic sclerosis and chronic Bright's disease, but may also occur in cases of senile arterial degeneration with a normal blood pressure. Syphilitic arteritis, though commonly leading to thrombosis, is a rare cause of cerebral hæmorrhage. Hæmorrhage into the brain may occur in any one of the blood diseases in which there is a liability to bleeding, such as scurvy, purpura and hæmophilia. It also occasionally happens that a congenital aneurysm of one of the cerebral arteries ruptures into the cerebral substance instead of into the subarachnoid space as is more common, and this should be remembered as a possible cause of cerebral hæmorrhage in young persons with normal arteries and blood pressure. Hæmorrhage may also occur into a vascular tumour of the brain such as an angioma.

Seats of Hæmorrhage. Scarcely any part of the brain is exempt from the risk of hæmorrhage, but it is much more frequent at the base in the neighbourhood of the corpus striatum and optic thalamus, which are mainly supplied by the branches of the middle cerebral artery, to which reference has already been made (see p. 605). Vessels may also burst in the lateral ventricles (*ventricular hæmorrhage*), or on the surface of the brain (*meningeal hæmorrhage*); but when blood is found in these situations, it has often proceeded from a hæmorrhage primarily in the cerebral substance.

Morbid Anatomy. In different circumstances the blood effused may be small in quantity or amount to several ounces. In the latter case it tears up the cerebral tissue, destroying, for instance, the great ganglia and the internal capsule, and extending thence into the centrum ovale, or it may burst through the optic thalamus or caudate nucleus into the lateral ventricle. Thence the

blood flows by the aqueduct of Sylvius into the fourth ventricle. Such cases are rapidly fatal, and post-mortem examination reveals a mass of dark red clot, filling the ventricle and occupying much of the hemisphere, surrounded by brain substance, which is ragged and discoloured by blood. In cases which have lasted a few days there is the same black-red clot, and the tissue around is soft and discoloured yellow, from absorption of hæmoglobin. The effect upon the parts of the brain not immediately destroyed by the hæmorrhage varies with the amount of the effused blood, and is due to pressure upon and consequent anæmia of the surrounding parts. This effect at first is local, but in the case of a large effusion rapidly becomes generalised, with consequent flattening of the convolutions and obliteration of the sulci. In cases which survive the clot gradually shrinks and becomes softened and yellow, this change proceeding inwards from the periphery, and is eventually absorbed. Meanwhile, the destroyed nervous elements in the surrounding brain tissue are broken up and destroyed by scavenging cells, and proliferation of the neuroglia proceeds to the formation of a wall surrounding the cavity or of strands which intersect it. The cavity may thus finally be obliterated with the formation of a puckered neuroglial scar, or it may remain in the form of a single or multilocular cyst containing serous fluid. The scar tissue frequently retains a yellow discoloration from the altered blood pigment. Destruction of the descending nerve fibres or their cells of origin leads to secondary degeneration, which is most easily followed in the course of the pyramidal tracts.

Symptoms. Cerebral hæmorrhage may be preceded for days or weeks by occasional giddiness, numbness or twitching of the fingers, headaches, insomnia, or some diminution of mental capacity; but these are not so much indications of the severe attack to come as evidences of existing disease of vessels, and perhaps due themselves to slight hæmorrhages. On the other hand, it may come on without any warning whatever. Sometimes it seems attributable to a definite cause, such as emotional excitement, muscular effort, violent coughing, or straining at stool; but at others it occurs when the patient is perfectly quiet, or even during sleep. In numerous cases cerebral hæmorrhage causes a group of symptoms known as *apoplexy*—that is, the patient is struck down suddenly unconscious, or he quickly becomes so (*ἀποπλήσσειν*, to strike to earth). Patients have died in five or ten minutes from the first symptom. More often the symptoms come on slowly. The patient is seized with intense pain in the head, becomes faint or slightly collapsed, may be sick or have a slight convulsion, and then, after half an hour or more, gradually sinks into a condition of coma. Or the first symptoms may show themselves in the motor system: the patient mumbles in his speech, or his arm drops powerless, and he gradually leans over to one side, falling if not supported, and then lapses by degrees into coma. Or the coma may be developed in a few hours through stages of increasing drowsiness, or the attack may begin with convulsions. In some cases the collapse is extreme, and the pulse is barely perceptible; but after an hour or two it improves and becomes full and bounding as the patient assumes the condition described below with complete coma and paralysis. Cases in which some hours elapse before the coma is complete have been called *ingravescent apoplexy*. When the patient is found by the friends alone, or is picked up in the street unconscious, or is unable to be roused in the morning from sleep, it is of course impossible to say what the onset has been. But undoubtedly cerebral hæmorrhage may occur without apoplexy; a very slight bleeding into the motor tract alone may give rise to paralysis without loss of consciousness, but this is uncommon.

The patient suffering from hæmorrhagic coma lies completely unconscious, and cannot be roused by shouting or any form of stimulation of his skin. The face is flushed; the pulse is full and tense; the breathing is *stertorous*, a loud, snoring noise being made in consequence of the palate or tongue falling back

and impeding the passage of air into the chest. The condition of the limbs varies : both legs and arms may be quite flaccid, falling at once when raised, or it may be obvious that the leg and arm on one side are more flaccid than those on the other. The muscles of the face share in the paralysis, and the cheeks are puffed out and sucked in with the processes of respiration ; this may also occur only on one side. Sometimes, however, the limbs of one or both sides are in a condition of rigidity (*early rigidity*), the muscles contracted and resisting extension or flexion. The deep reflexes are commonly increased, and the skin reflexes are absent. The plantar responses are the first to return and are then usually extensor. The pupils are variable : they are sometimes contracted, at others dilated or unequal. Conjugate deviation may occur. The temperature shows a slight fall, which may continue till death, or if life is prolonged it rises a little above the normal. A greater or persistent fall of temperature, like a rapid or excessive rise of temperature, is of ominous significance. The latter is often associated with rupture into the lateral ventricles. Sugar is occasionally found in the urine, from pressure on the medulla oblongata. A trace of albumin is commonly present in association with primary contracted kidneys. In very severe cases the pulse and breathing are rapid, there is profuse sweating, and intense flushing of the face and skin generally ; then after a time, two or three hours or more, the patient becomes livid, râles occur in the larger bronchi and trachea, the pulse gets weaker, the breathing slower, and finally death takes place. The fatal termination may, however, be delayed for several days, during which the lungs are very apt to suffer from œdema or pneumonia ; and the occasional passage of particles of food or fluids through the glottis probably contributes to the inflammation of these organs. In more favourable cases, the patient lies simply comatose, with but little disturbance of his pulse or respiration, and gradually regains his senses in the course of a few hours or two or three days. In a large proportion of cases, the patient is then found to be suffering from *hemiplegia*, which may itself slowly recover or be permanent.

Diagnosis. This has to be made from other conditions, causing a sudden onset either of coma or the signs of a cerebral lesion, and will best be considered after cerebral thrombosis and embolism have been described.

Prognosis. This is generally unfavourable in proportion to the extent of severity of the first symptoms. That apoplexy is often fatal is well known, and death may take place at different intervals after the onset. The cases are grave in which the coma is profound, with much stertor, flushed or congested face, full bounding pulse, and complete relaxation of all the limbs. A temperature which rises steadily during the first thirty-six hours is usually a sign of hæmorrhage into the ventricles and a fatal issue.

If, after recovery from the first coma, headache continues, and the patient again becomes drowsy, the result is likely to be serious.

Treatment. If the case is seen early and the diagnosis is certain venesection is theoretically the correct treatment, for the fall of blood pressure thus produced may arrest the flow from the ruptured vessel and give time for coagulation to occur. Practical experience, however, shows that cerebral thrombosis, as well as cerebral hæmorrhage, may occur in a person with a high blood pressure and hypertrophied heart, and the differential diagnosis is largely a matter of conjecture. Venesection is, perhaps, as likely to do harm in thrombosis as to help in hæmorrhage. As a general rule, therefore, it is perhaps better avoided. In the case, however, of a person of middle age previously known to have a systolic pressure over 200 mm. Hg. without signs of cardiac failure, the chances of hæmorrhage as opposed to thrombosis are high, and prompt removal of a pint of blood is the right course.

The essential part of treatment in all cases is complete rest until such time as it may be assumed that the ruptured vessel has healed. The patient should be

put to bed with as little disturbance as may be. If he is unconscious he should be laid on his side, care being taken that his head does not drop forward and impede the circulation in the large veins of the neck. The skin should be carefully tended. The patient should not be allowed to remain on one side too long, and if he is heavy a water-bed is advisable. He may be incontinent, but if there is retention catheterisation is necessary. During the first twenty-four or forty-eight hours purgatives are better avoided. Their administration to an unconscious patient is difficult and their action disturbing. If the patient is known not to have had his bowels open recently an enema may be given at the end of twenty-four hours. If he is in a restless semi-conscious condition sedatives should be given. Chloral hyd. gr. xv. with pot. brom. gr. xxx. in a single dose, to be repeated if necessary, is suitable by the mouth. If the patient cannot take this and is restless morphia should be given, for although it has a depressing action on the respiratory centres rest is most important, and restlessness itself an indication that the degree of pressure upon the vital centres is not dangerous. If the patient is conscious he should be laid upon his back with head and shoulders supported on a pillow. The room should be darkened and kept quiet and visitors forbidden. It is probably wise to starve the patient for the first twenty-four hours, water being given in sips from a feeding cup. After this fluid feeding can be commenced by the mouth if he is conscious, or per rectum after a preliminary enema to clear the bowel. A light diet should be enforced for some days or weeks. In a severe case the patient should be kept in bed for at least a month from the onset, and even in a slight case rest in bed for a fortnight is advisable. In the case of paralysed limbs massage and movements should not be begun until three weeks have elapsed, except that very gentle passive movements of the joints may be performed night and morning to prevent adhesions. At the end of this time, massage, passive movements and especially active movement, should be carried out daily. Electrical treatment in a case of hemiplegia is of no value. After an attack of cerebral hæmorrhage the patient's mode of living should be regulated according to the cause. (See Hyperpiesia.)

CEREBRAL EMBOLISM AND THROMBOSIS

Pathology. The usual cause of *embolism* is endocarditis. In ulcerative or infective endocarditis the embolus is formed by a fragment detached from one of the vegetations upon the valves. In chronic mitral stenosis with a dilated left auricle clot may form in the auricular appendix, and a portion of this being broken off and delivered into the blood stream may form an embolus. Embolism from mitral stenosis occurs as frequently without as with the association of auricular fibrillation. Another and much less frequent cause of central embolism is the passage of a clot from one of the systemic veins (*e.g.* saphenous, femoral or pelvic) through a patent foramen ovale. Occasionally after coronary thrombosis a portion of clot formed within the left ventricle may become detached and cause embolism.

The middle cerebral artery is more often affected by embolism than the others, and the left more often than the right.

Thrombosis is most frequently caused by disease of the vessel wall, such as atheroma, by which the surface is roughened, and fibrin is consequently deposited. Syphilitic disease of the arteries produces considerable narrowing of their channels, and thus favours thrombosis. In addition, thrombosis may occur from several conditions weakening the circulation, such as those resulting from enteric fever, typhus, cancer, phthisis, and other severe illnesses. It may also occur in erythræmia.

Embolism and thrombosis, by obstructing the circulation of the blood, alike lead to *softening* of the districts of the brain to which the vessels correspond, unless the vascular supply is maintained by means of anastomoses. These are

not abundant in the case of the cerebral vessels, and, indeed, the vessels going to the central ganglia are really terminal vessels, while those going to the cortex of the brain anastomose more or less. At least, this is true of the distribution of the middle cerebral artery—the vessel most often obstructed. A part of the brain in which softening has taken place has generally lost the smooth, glistening surface of a normal brain section, is more opaque, or grey, or speckled; it breaks down readily under a stream of water; or it is milky or diffuent. It shows under the microscope drops of myelin, portions of nerve fibres, large mononuclear phagocytes containing granular *débris*, and free fat globules. It sometimes has a yellowish or brownish colour from altered blood pigment; or minute extravasations of blood may be present in cases of sudden obstruction, and a form of *red softening* results. In cases of rapid death after embolism, the brain substance may look perfectly healthy, as there has not been time for any changes visible to the naked eye to take place. Occasionally an embolus sets up inflammatory changes in its neighbourhood; sometimes it leads to aneurysm and cerebral hæmorrhage, as already described. Rarely actual infarcts are formed. The later stages of softening consist in the absorption of the disintegrated tissue, and the formation of a cyst; or, if the softening is small, a cicatrix may be produced.

Thrombosis or embolism, involving the motor tract, are followed by the same secondary changes as are hæmorrhagic lesions.

Symptoms. The results of *embolism* are not very different from those of hæmorrhage; but it more often causes sudden hemiplegia without loss of consciousness than does hæmorrhage. Obstruction of a large vessel will cause sudden loss of consciousness, and death may take place soon after. Since the softening occurs only in the areas supplied by the vessel beyond the seat of obstruction, the symptoms are more likely to correspond with the distribution of the artery than in hæmorrhage, where the extravasated blood ploughs up the brain with little discrimination. If the middle cerebral be obstructed near its origin, there will be hemiplegia of the opposite side, and if the lesion is on the left side, aphasia also, since this artery supplies the internal capsule, Broca's convolution, the greater part of the motor area of the cortex, the first and second temporal convolutions, and the angular gyrus. Persistent hemiplegia is accompanied by the conditions already mentioned (*see* p. 607).

Thrombosis is usually less rapid in its effects, though with the same results—apoplexy and hemiplegia; but sometimes a sudden coma occurs, indistinguishable from that of hæmorrhage. There are often premonitory symptoms—headache, dizziness, loss of memory, drowsiness, numbness, or formication of an arm or leg, or of one side of the body.

Diagnosis of Cerebral Vascular Lesions. This may be divided into two heads—the diagnosis of apoplexy from other conditions simulating it and the diagnosis from one another of the different causes of apoplexy or hemiplegia.

1. In the former the history is of great importance. Causes of coma occurring in the course of severe illnesses, such as meningitis, cerebral abscess, cerebral tumour, typhoid fever, etc., may be readily excluded by the history; it is coma coming on suddenly or rapidly which may be confounded with apoplexy. In *pyæmia* a sudden coma has sometimes occurred closely resembling that of apoplexy. More commonly the conditions to be discriminated from it are coma from injury, poisoning by opium, alcoholic poisoning, uræmia, diabetes, epilepsy and heart-block. In hot countries it will be necessary to remember that coma arises from heat stroke and pernicious malaria.

Cases of *injury*, in the absence of history, may present the greatest difficulties, as, even with the external evidence of injury, it may remain uncertain whether the patient has fallen as a result of apoplexy, or has injured his brain in consequence of the fall. Even after death the problem may be insoluble. The position of a scalp wound in relation to the weaker side, if paralysis can be recognised,

may sometimes help ; and the age of the patient, or other circumstances of his bodily health, may render a spontaneous lesion of the brain more or less likely. In cerebral concussion the patient is pale, with dilated pupils and low blood pressure. His limbs are flaccid. Recovery is usually heralded by vomiting. In sub-dural hæmorrhage there are symptoms of *compression*, with slow pulse ; there is gradually deepening coma with remissions, during which the patient is quite conscious.

Opium poisoning is generally distinguished by the minutely contracted pupils, the slow pulse, and slow respiration ; but it may be closely simulated by hæmorrhage into the pons Varolii. Evidences of a unilateral lesion, such as greater flaccidity or rigidity of limbs on one side, or unequal pupils, are in favour of hæmorrhage. In *poisoning from other hypnotic drugs*, such as chloral or the barbiturates, the respiratory rate and depth are often increased, and the pupils dilated and reacting sluggishly to light. The same may be said of *alcoholic poisoning*. The condition is one of profound coma, without any one-sided symptoms. Evidence of alcohol may, of course, be obtained from the breath, or from the stomach by means of emetics or the stomach tube. But a patient may have drunk freely or sufficiently just before an apoplectic attack, or if the attack has come on gradually he may have taken a glass of spirits as treatment.

Asthenic uræmia is accompanied by albuminuria, but the detection of albumin in the urine does not exclude cerebral hæmorrhage, for, in the first place, hæmorrhage occurs often in those who have granular kidneys ; and, secondly, hæmorrhage may itself produce albuminuria in those who have healthy kidneys. In uræmia sometimes the coma is less profound ; the patients are more easily roused for a time by shouting, to relapse again into coma. There is no paralytic weakness, no vasomotor disturbance, and no flush of congestion, such as occur in some cases of apoplexy. Addison used to call attention to the hissing nature of the breathing. Uræmia will be indicated by a large increase of urea in the blood (see p. 530).

Diabetic coma develops very slowly, and is not profound till near the end ; it is often preceded by severe abdominal pain, so severe sometimes as to have led to a diagnosis of perforation of the intestine. The pulse is rapid and feeble, the breathing is often slow, deep, or sighing, and the breath has a sweet odour. The urine contains sugar and aceto-acetic acid ; but here also a mistake is possible, for a hæmorrhage involving the fourth ventricle may produce glycosuria.

A *major epileptic attack* is commonly followed by coma, which is more like natural sleep than that of apoplexy ; there are no unilateral symptoms, but both plantar responses may be extensor. Apart from a previous history of epilepsy, the presence of a recently bitten tongue, or of minute hæmorrhages beneath the skin, conjunctiva or mucous membranes may be of diagnostic value. If the onset of the attack has been witnessed by the patient's friends the story of tonic or clonic spasms at the onset is usually obtainable, and conclusive.

Hypoglycæmic coma, which may be accompanied by epileptic attacks, is usually the result of an overdose of insulin, but may occur as the result of other disease (see p. 479). Occasionally *hysterical* patients will lie unconscious for long periods, but the cases are generally distinguished by other characteristic symptoms.

The chief feature in *heart block* is the extremely slow pulse (see p. 232). There may be convulsions, and the breathing is deep and rapid.

Sub-arachnoid hæmorrhage is sometimes distinguished with difficulty from an intra-cerebral vascular lesion. In both cases the onset may be apoplectic, but in sub-arachnoid hæmorrhage, unless the effusion has torn its way into the brain, there are no unilateral signs, and as the patient begins to emerge from coma, neck stiffness and Kernig's sign are discoverable, and there is abundant blood in the cerebro-spinal fluid obtained by lumbar puncture.

2. In the diagnosis of the causes of apoplexy, one has to consider the nature of the attack and the associated condition of the patient. It will have been seen

that the nature of the attack often gives but little help. Hæmorrhage, embolism, and thrombosis may all produce a sudden or rapid coma. The more severe and prolonged the coma the greater the probability of hæmorrhage, whereas a pronounced hemiplegia, occurring without coma or with very transient unconsciousness, is more likely to be due to embolism or thrombosis. Age is in favour of hæmorrhage, and youth almost excludes it except from a congenital aneurysm; but in persons between forty-five and sixty years of age positive indications in one or other direction are often wanting. In ventricular hæmorrhage evidence of blood will be found in the liquid withdrawn by lumbar puncture.

The associated conditions of hæmorrhage are albuminuria and other evidences of renal disease, or arterial degeneration, with tense and rigid or thickened arteries, high blood pressure and a hypertrophied heart. Senile changes in the arteries may also be recognised in many cases of thrombosis. Hemiplegia in young subjects free from heart disease is often due to syphilitic arteritis, of which further evidence may be found in the history, or in the Wassermann test. In embolism there is generally a mitral or aortic murmur, or some evidence of dilatation of the left cavities of the heart, which serves as a source of the embolus, or there may be signs of embolism in other parts of the body, such as enlargement or tenderness of the spleen, blood in the urine, the characteristic appearances in the retina, or obstruction of an artery in one of the limbs. Other less common causes of apoplexy with hemiplegia are general paralysis of the insane, hæmorrhage into a cerebral tumour, infective encephalitis and the rupture of an intracranial aneurysm into the substance of the brain.

Treatment. If cerebral embolism or thrombosis can be certainly recognised, the treatment is similar to that of cerebral hæmorrhage; but venesection must not be thought of. Absolute rest, milk diet, ice to the head if there is pain, and gentle laxatives or enemas if the bowels are confined, are the main indications.

The treatment of the resulting hemiplegia is also the same.

CHRONIC CEREBRAL SOFTENING

Disease of the cerebral arteries, besides causing such relatively severe and sudden symptoms as have already been described, may lead to a gradual deterioration of cerebral function without any apparent seizure. This may result from the sum of repeated small vascular lesions or from a gradual and diffuse process of decay.

Pathology. Arterial thickening and decay of the varieties already described is the basis of the morbid condition. To the naked eye the brain may show multiple areas of softening or may simply appear shrunken. Under the microscope smaller areas of softening are apparent. In the affected areas the nerve cells and fibres are degenerated. The myelin is broken up into fatty droplets, which are removed by scavenging cells, and there is a variable amount of neuroglial reaction.

Symptoms. The symptoms vary according to the parts of the brain chiefly affected, but since the process of decay is usually widespread mental deterioration is often prominent. This takes the form of defective memory, especially for recent events, and difficulty in concentration. These symptoms are, as a rule, apparent to the patient, who will often complain of them. Loss of emotional control with short-lived moods of depression, irascibility and more rarely of elation, and disturbance of sleep, are other symptoms. Epileptic attacks may occur and may be of a generalised or focal type. Optic atrophy may occur with failure of vision as the leading complaint. Involvement of the pyramidal fibres on both sides of the brain not infrequently leads to loss of voluntary control over the muscles supplied by the cranial nerves, and of these the palate, tongue and pharynx are most often involved, with consequent dysarthria and dysphagia, the

condition being known as *pseudo-bulbar paralysis* to distinguish it from that form of bulbar palsy which is due to disease of the lower motor neurons, and has already been described. (*See also Pseudo-uræmia.*)

Sensory symptoms are uncommon, but the motor functions may be interfered with in various ways. If, as commonly happens, the pyramidal fibres are chiefly involved, the picture is that of a progressive double hemiplegia, the spasticity and weakness being usually more marked in the lower than in the upper limbs. Or the basal ganglia may be affected with consequent development of rigidity, weakness and tremor of the kind seen in *paralysis agitans*. The cerebellar functions also may be involved. In the case of pyramidal involvement the deep reflexes are increased, including, in the cases of pseudo-bulbar paralysis, the jaw-jerk, and the plantar responses are extensor. The history may be of an insidious onset, but careful enquiry will often elicit a story of attacks of giddiness or faintness, probably representing minute vascular lesions.

Diagnosis. The age of the patient and the condition of his arteries are as a rule the guides to a correct diagnosis. In a middle-aged patient a high blood pressure may be the important clue, and ophthalmoscopic examination of the retinal vessels will often provide valuable evidence of arterial disease.

The differential diagnosis has to be made from other causes of slowly progressive cerebral disease, such as syphilis and tumour, and from the neuroses.

Prognosis. This is necessarily bad, the symptoms tend to progress slowly and the patient with cerebral softening is always liable to an outspoken attack of cerebral hæmorrhage or thrombosis.

Treatment. This must be to a large extent symptomatic. The general régime should be that already laid down for patients suffering from arteriosclerosis (*see pp. 301, 304*), mental fatigue in particular should be avoided, and the patient advised to rest on his bed for an hour in the middle of the day. Sedatives and hypnotics should be given as required to control irritability and insomnia.

THROMBOSIS OF THE CEREBRAL SINUSES

The blood coagulates in the cerebral sinuses either as a result of some profound cachexia, or in consequence of infection from lesions of adjacent parts.

The former causes mostly an adhesive thrombosis, the sinus being obstructed by laminated clot, without any general infection of the system. It occurs most often in infants, especially those suffering from marasmus or chronic diarrhœa. It mostly affects the *longitudinal sinus*. Coma, rigidity of the neck, trunk or limbs, twitching of the muscles, and epileptic attacks are the main symptoms, and if there is recovery bilateral spastic weakness results which is most marked in the lower limbs.

The morbid appearances associated with thrombosis of the longitudinal sinus are highly characteristic. The large veins in the pia-arachnoid are thrombosed and stand out like dark cords. The veins on the inner surface of the dura as they enter the sinus are also distended.

Thrombosis from *local infection* is mainly caused by extension from disease of the ear, but the origin may be in the orbit, nose, mouth, pharynx, or other part from which the lateral or cavernous sinus can be reached.

Lateral sinus thrombosis is generally the result of otitis media and mastoiditis. The onset is usually marked by a rigor, which may be repeated at the peaks of a swinging temperature. The thrombosis may extend into the jugular vein, which is then felt as a hard swelling below the mastoid process in the neck.

Thrombosis of the cavernous sinus may be secondary to infection of the nose, cheek, eye or nasal sinuses. Rigors and fever are less constant and prominent features than in lateral sinus thrombosis. There is proptosis of the eye, œdema of the conjunctiva and eyelids, and frequently paralysis of the ocular muscles

from involvement of the third, fourth and sixth cranial nerves. Papilloedema may be present but is inconstant. The condition is usually bilateral and fatal.

In these infective cases septic particles are frequently conveyed into the right heart, and thence into the lungs, so that a fatal pyæmia is the result.

Treatment. In thrombosis dependent on general ill-health, this condition must be treated. If local lesions are the cause, they must be dealt with surgically. The spread of an infective thrombus down the jugular vein can be prevented by tying the vein below the clot and clearing out its contents, as well as those of the lateral sinus, if necessary.

SUB-ARACHNOID HÆMORRHAGE

Hæmorrhage in connection with the cerebral membranes may be between the bones of the skull and the dura mater (*extra-dural*), within the dura mater but outside the arachnoid membrane (*sub-dural*), or within the sub-arachnoid space (*sub-arachnoid*).

The first two are almost invariably traumatic and are dealt with in works on surgery. The symptoms of a chronic sub-dural hæmatoma which may present considerable difficulties in medical diagnosis are dealt with under the head of pachymeningitis interna hæmorrhagica (see p. 693).

Ætiology. Sub-arachnoid hæmorrhage may occur spontaneously as the result of rupture from any cause of a superficial vessel. The common cause in elderly persons is arterial disease with hæmorrhage either direct or with the preliminary formation of a small aneurysm. In young persons with healthy arteries the cause is usually the rupture of a congenital aneurysm. Such aneurysms are by no means uncommon, being found at the junctions of the circle of Willis or the bifurcation of its main branches, presumably as the result of a defect in development. They are often of minute dimensions and readily missed at a post-mortem in a case of sub-arachnoid hæmorrhage unless specially looked for. Aneurysm of the cerebral arteries with subsequent rupture may also result from embolism in infective endocarditis, and is another cause of sub-arachnoid hæmorrhage. It may also occur, though rarely, in the various conditions such as hæmophilia and purpura, in which spontaneous bleeding may happen.

Morbid Anatomy. In a fatal case the whole sub-arachnoid space is filled with blood, which extends in a thin sheet over the hemispheres, lies in greater depth in the basal cisterns, and wells up from the spinal sub-arachnoid space when the brain is removed. Patient search will usually reveal the source of hæmorrhage in the case of an aneurysm, but unless this is especially looked for it may be missed.

Symptoms. In elderly persons with disease of the cerebral arteries there are often preliminary symptoms of the same kind met with in cerebral hæmorrhage (*q.v.*). In others and in young persons with congenital aneurysms the onset is dramatic. If the rupture is a large one the patient may fall suddenly to the ground unconscious. More usually there is abrupt complaint of severe headache or pain in the back of the neck with subsequent loss of consciousness. The duration and depth of coma vary with the size of the effusion. If the rent is a large one the patient may die within a few hours without recovery of consciousness. In the case of a smaller leakage consciousness is regained and signs of meningeal irritation appear in the shape of pain and stiffness in the back of the neck and a positive Kernig's sign. The tendon reflexes at this stage are frequently lost and the plantar responses extensor. The optic discs are frequently engorged and sometimes show large retinal and sub-hyaloid hæmorrhages. If improvement continues these signs of meningeal irritation gradually pass away in the course of two or three weeks. During the earlier stages of this period there is irregular pyrexia and usually some delirium. In the case of a small hæmorrhage there may be no loss of consciousness at the onset, the leading symptoms from the first being headache and the evidences of meningeal irritation.

Lumbar puncture within a few hours of the onset will give spinal fluid mixed with fresh blood, which will clot in the test tube if allowed to stand, leaving a clear and colourless fluid above. By the end of twenty-four hours coagulation has begun to occur at the site of hæmorrhage and the red cells are disintegrating. The spinal fluid at this stage, if allowed to stand, shows no clot, but a sediment of red cells with a slightly golden-yellow supernatant fluid. During the subsequent few days this golden-yellow tinge becomes more evident.

Diagnosis. This has to be made in a severe case with prolonged coma from cerebral hæmorrhage and the conditions which may resemble it (*see* p. 696), and in the milder cases in which the signs of meningeal irritation predominate from meningitis. In meningitis, however, the onset is hardly ever so acute. The question, if in doubt, may be settled by lumbar puncture.

Prognosis. Recovery from a small leak is not uncommon. Leakage from a congenital aneurysm may occur on several occasions in a period of years, but is probably always fatal in the end. In hæmorrhage from other causes the prognosis depends largely upon the underlying condition.

Treatment. This is the same as for cerebral hæmorrhage, with the exception that lumbar puncture offers an opportunity of draining the effusion. This procedure is not without danger of provoking fresh leakage from a healing rent, and should therefore be undertaken only when persistent or deepening coma indicate a large or progressive effusion with danger to life from cerebral compression. A manometer should be used and the pressure of the spinal fluid should not be allowed to fall below 100 m.m. of water.

ENCEPHALITIS

The brain is, like other organs, subject to inflammation from the invasion of micro-organisms or their toxins, the condition being known as encephalitis. In the case of the pyogenic organisms this proceeds rapidly to the formation of a cerebral abscess. In other instances the inflammatory process may continue without suppuration towards a fatal issue from involvement of the vital nerve centres. The virus may be one with a selective action upon the brain, as for instance in encephalitis lethargica, or the encephalitis may occur as a complication or sequel of a more generalised infection, *e.g.* measles encephalitis. The brain may be affected alone or together with the spinal cord (encephalomyelitis).

Of the various diseases in which encephalitis may occur some have already been described. Thus it may happen, though rarely, that the brain is involved in poliomyelitis and it is constantly affected in disseminated sclerosis. The less common varieties of encephalitis will be briefly described in the succeeding paragraphs. Encephalitis lethargica will be described later.

Encephalomyelitis of Measles. This is a rare complication. The onset is usually on the fourth to sixth day of the disease after the fever has fallen and the rash has begun to fade. Drowsiness, headache, twitching and convulsions are the usual symptoms of onset. With these there is a recrudescence of fever, and the disease may go on to produce paralysis, of which the commonest form is a hemiplegia. The spinal fluid usually shows a moderate increase of lymphocytes. The mortality amounts to 10 per cent., and more than half of those that survive show residual symptoms in the form of weakness, ataxia, mental change or epilepsy. Pathological examination shows as the characteristic feature zones of demyelination around the small veins. With this may be associated perivascular exudation of lymphocytes and plasma cells.

A similar encephalomyelitis may occur as a late complication of *chicken-pox*. In these cases the prognosis appears to be good and records of pathological examination are lacking.

Vaccinal Encephalomyelitis. A number of cases of this disease have been

reported in this country and on the continent of Europe during the past few years. The clinical story is usually that of a successful and uncomplicated vaccination, followed about fourteen days later by the sudden development of signs of nervous affection. These are meningeal, cerebral and spinal, with a major incidence upon the pons and lumbo-sacral enlargement. The illness commonly begins with headache, fever, vomiting and drowsiness; diplopia and symptoms due to paralysis of other cranial nerves then develop, often together with paralysis of the lower limbs and loss of sphincter control. The cerebro-spinal fluid shows a moderate lymphocytosis. The mortality is high, the patient frequently dying comatose within a few days of the onset, but recovery when it occurs is usually complete. Pathological examination in fatal cases shows the presence of scattered areas of perivascular demyelination throughout the spinal cord, brain-stem and brain.

Other Forms of Encephalomyelitis. A number of other varieties of encephalitis or encephalomyelitis have been described and have been named after the distinguished physician who has described them (*e.g.* Strumpell's Encephalitis), or the part of the nervous system chiefly attacked (*e.g.* Polio-encephalitis acuta inferior). Such distinctions, however, would appear to have no real value, and in the present state of our knowledge we must admit the occurrence of sporadic cases, and from time to time small local epidemics, of what may be called acute meningo-encephalomyelitis. Such illness is, perhaps, commoner among children, but may be met with at any age. The leading symptoms may be those of a meningitis, encephalitis or myelitis, and the diagnosis can only be arrived at by a process of exclusion which frequently involves a period of prolonged observation. The cerebro-spinal fluid in these cases may show a moderate lymphocytosis, but is often normal. The prognosis on the whole is good, but in infants and young children a persistent hemiplegia is not uncommon and is sometimes associated with epilepsy.

ENCEPHALITIS LETHARGICA

(*Epidemic Encephalitis*)

This is an acute or subacute non-suppurative inflammatory process affecting the nervous system and meninges in a widespread disseminated fashion. It most commonly involves the structures of the mid-brain, giving rise in the first place to symptoms of lethargy and paralysis of the oculomotor nerves, and at a later stage weakness, tremor and rigidity of the type originally described by Parkinson in Paralysis Agitans. In a large number of the cases the inflammatory process becomes chronic and may progress slowly over a period of years.

The disease first appeared in epidemic form in Vienna in 1917; one year later it became widespread throughout the whole of Europe, and in the following year spread to America.

Persons of all ages are liable to infection. It attacks the population in a widespread random fashion; only in rare instances has more than one case been reported from the same household, and there is no evidence so far to show that it is directly communicable from one person to another. From the time of its first appearance mild outbreaks in epidemic form continued to occur every year in the winter and spring, with sporadic cases during the intervening periods. The greatest number of cases in this country occurred in the spring of 1924. Since 1925 sporadic cases only have been reported, and the disease in its acute form would appear at the present time (1935) to have died out.

Although the disease was not recognised as a specific entity until 1917, small epidemics of a similar nature were reported in Central Europe following the influenza epidemic in 1890, and it is probable that isolated cases have passed unrecognised since that time.

A number of investigators, Levaditi and Harvier in France, Macintosh and Perdrau in this country, and Strauss and Loewe in America, have recorded the

successful inoculation of animals with the disease by injection of material from the brains of fatal human cases. Levaditi and Harvier also obtained positive results from swabbings of the nasal mucous membrane in an acute case. The disease produced in animals from either source could be transmitted by inoculation through a series of animals from month to month. The organism has not been cultured and appears to belong to the group of filterable viruses.

Morbid Anatomy. On macroscopic examination the brain and spinal cord show in the majority of cases little abnormality beyond congestion of the capillaries, which is generally best marked in the grey matter of the basal ganglia, mid-brain and cerebral cortex. In some instances extravasations of blood are seen either in the subdural or subarachnoid spaces, or in the substance of the mid-brain.

Under the microscope in a case proving fatal within ten days of the onset there may be nothing more to see than intense capillary congestion. Later in the course of the infection, in addition to congestion, there appear other changes characteristic of the disease. The walls of the smaller vessels are seen to be infiltrated with small round cells, and the perivascular spaces filled with them, which leads to the appearance, on cross section of a capillary, of a cuff of lymphocytes surrounding the vessel. Among these small cells are seen occasional large cells containing granular pigment. The nerve cells in most cases show evidence of degeneration, but are attacked in a somewhat random manner, so that in a single nucleus of grey matter only a small proportion of the cells are affected. The changes seen are swelling and excentricity of the nucleus, breaking up of the Nissl granules (chromatolysis), and invasion by small round cells (neuronophagia). These changes are most constantly found in the grey matter of the mid-brain and pons and the basal ganglia, but may also be discovered in the cerebral cortex and the spinal cord. Capillary congestion and round-celled infiltration have also been described in the roots of the cranial and spinal nerves. No constant changes are found in the other organs of the body.

In cases of the chronic progressive variety exhibiting the Parkinsonian syndrome the maximal destruction is found in the substantia nigra of the mid-brain, where traces of an active inflammatory process may still be seen.

Symptoms. 1. *Early Stage.* These may be divided into those of general intoxication and those referable to localised lesions in the central nervous system. Under the former heading are included pyrexia, malaise, anorexia, vomiting, general pains, and occasionally an erythematous rash. The nervous symptoms are extremely variable, depending upon the localisation of the virus, which may involve any part of the nervous system or its coverings. In the large majority of cases, however, the main incidence is upon the mid-brain, and gives rise to characteristic signs. The disease as a rule commences insidiously with a feeling of lethargy and drowsiness. With this are frequently associated minor signs of meningeal irritation, such as headache (often suboccipital) and stiffness of the neck. In the course of a day or two the nuclei of the third nerves become affected, leading to dimness of vision for near objects due to paralysis of accommodation, ptosis, and weakness of the ocular movements; at this stage complaint is sometimes made of diplopia. Subsequently the drowsiness progresses, until the patient appears to be continually in a stuporous condition, from which he must be roused to take his food. When awakened, however, his mental condition is quite clear, and he is able to answer questions in a rational manner. At this period of the illness the picture presented is a very striking one. The face appears to be smoothed out and expressionless, and this, combined with the ptosis, gives rise to an appearance of inanimate stupidity, against which the lucidity of the mental state often stands out in remarkable contrast. Careful observation will often reveal the occurrence of irregular twitchings at this stage, affecting individual muscles or their fasciculi in random fashion, but seldom powerful enough to move the limbs. These may involve any part of the musculature, including that of the

trunk and face. The tongue is dry and coated, and frequently tremulous. The patient may complain occasionally of pains in the limbs.

The temperature at the onset is raised, and oscillates in an irregular manner between 99° and 101° , with corresponding alterations in the pulse rate. In a fatal case the temperature as a rule rises, the stupor deepens into coma, incontinence of fæces and urine follows, and death occurs in from ten to twenty-one days from the onset.

Physical examination when the disease is well developed may reveal additional signs. Thus the pupils are frequently unequal, and respond sluggishly to light. If the patient can be induced to co-operate in the examination, it is commonly found that the pupillary reaction in accommodation is lost, together with the power of convergence. Not infrequently there is paralysis of other ocular movements. Nystagmus is often present. The Argyll-Robertson pupil may occur.

The other cranial nerves are not affected as a rule. No anomalies of sensation are discovered beyond the complaints of pain already referred to. Examination of the motor system reveals general muscular weakness, combined sometimes with plastic rigidity, so that the limb will remain almost indefinitely in any attitude in which it is placed, however bizarre (catatonía). The reflexes vary from case to case; the tendon reflexes may remain unaffected; they may be increased; more frequently they are abolished; the abdominal reflexes seldom show any abnormality; the plantar responses are as a rule flexor.

If recovery ensues, the temperature begins to fall during the third week from the onset, and the patient gradually awakens from his stuporous condition. With the end of the third week the period of pyrexia terminates, but in a severe case lethargy persists, the cranial nerve palsies clear up slowly, and it may be three months or more before the normal functions of the nervous system are again fully established, if indeed complete recovery is attained.

Since the symptoms in a case of nervous disease depend almost entirely upon the localisation of the infective process, and since in the disease under consideration the distribution of the virus may be widespread, one must be prepared to find almost any combination of signs and symptoms in the course of an epidemic; with the extension of the inflammatory process from one part to another the appearance of a single case may change from time to time, and among half a dozen cases there may be no outstanding nervous symptom common to all. Thus, with regard to the onset, in addition to the common type already described there may be instances in which meningeal symptoms at first predominate; in other cases restlessness, irritability, or even a noisy delirium may take the place of the more usual lethargy; the illness may begin acutely with an apoplectiform seizure, or the picture may be entirely dominated by the presence of muscular twitchings (the so-called myoclonic type), usually associated with delirium. In another group of cases the disease may be ushered in by severe neuralgic pains of peripheral nerve or root distribution; these may be followed by wasting and weakness of isolated groups of muscles. Or, again, in some instances absence of tendon jerks and subjective sensations of numbness in the extremities may give rise to the appearance of polyneuritis.

This account by no means exhausts the symptomatology of the disease. Among signs of minor importance may be mentioned dysarthria, dysphagia, paroxysms of dyspnoea, hiccough, excessive salivation, excessive sweating, sensations of choking or stifling, retention of urine, and occasionally spasmodic contracture of the jaw muscles.

The extent and duration of pyrexia are variable; the temperature may have been raised during the initial stages, but on account of the insidious nature of the onset may have subsided before the patient comes under medical observation. In mild cases the signs of involvement of the nervous system are often fleeting, and special inquiry is necessary to elicit a history of transient diplopia, temporary

paralysis of accommodation, pain and stiffness in the back of the neck, neuralgic pains or muscular twitchings. In a great many patients presenting themselves with undoubted symptoms of the chronic progressive type no history of onset can be obtained.

The cerebro-spinal fluid is always clear; in about one half of the cases it shows no abnormality by the time it is examined, but in the other half there is an increase in the number of lymphocytes, which varies from ten to eighty cells per cubic millimetre; this lymphocytosis is more commonly observed in cases in which lumbar puncture is performed early in the course of the disease. There is, as a rule, no increase in the protein content, but the colloidal gold test may give curves of the paretic or luetic types. The Wassermann reaction in blood and cerebro-spinal fluid is negative.

2. *Late Stage.* In a large proportion of the cases after the acute stage has subsided further symptoms develop, as the result of a smouldering process of infection, which may continue to involve fresh areas of the brain for months or even years after the onset. In some cases the patient passes directly from the early into the late stage of the disease, but more often there is a latent interval during which he may appear to have made a satisfactory recovery—and this interval may be of several months' or even of several years' duration. The severity of his late symptoms bears no relation to that of the early stage, so that cases of a mild or ambulatory nature, which may not in the first place have been recognised, are often subsequently the victims of serious physical or mental disability. The commoner symptoms of the late stage may be grouped under the headings of (1) Weakness, rigidity and tremor of the paralysis agitans type, (2) Involuntary movements, (3) Mental changes.

(1) Symptoms resembling those of paralysis agitans probably develop in a high proportion of the cases which survive the early stage of the illness, and, as has already been stated, may appear without any history of initial infection. The most noticeable feature as a rule is the stiffness of the facial muscles with consequent loss of expression; the rigidity often involves also the muscles of trunk and limbs; the gait is then slow and shuffling, with bent back and bowed head, the arms are held stiffly with elbows slightly abducted and fingers semi-flexed. Automatic movements are diminished or lost, and the patient has difficulty in adjusting his centre of gravity, and his balance therefore is easily upset. Inhibition of the blinking reflex adds to the staring facial expression, and of the swallowing reflex to the dribbling of saliva. The voice is frequently monotonous and speech slow. Tremor of the paralysis agitans type may also be present, but is usually slight in comparison with the rigidity.

(2) Involuntary movements of all kinds may occur, but the proportion of cases in which they are a striking feature is small. Tremor of the paralysis agitans type has already been mentioned. Choreiform and athetoid movements are also seen. Perhaps the commonest type, however, is that in which there are rhythmic movements of relatively large amplitude and slow rate involving the musculature of the proximal joints (shoulder and hip), often affecting a single limb or the arm and leg on one side of the body. Another striking, and as a rule a late, sequel is the occurrence of forced upward movement of the eyeballs (oculogyric crises). These are paroxysmal, and as a rule without warning, lasting for minutes or hours at a time. Being beyond voluntary control they render the patient for the time being incapable of useful vision.

(3) Mental impairment of some degree is an almost constant sequel of the disease. In adults it is manifest in slight cases as an increased tendency to fatigue and diminished emotional control; in more severe cases symptoms of a neurasthenic character develop with constant complaint of headache, feelings of inadequacy and morbid anxiety. In the cases of the paralysis agitans type, on the other hand, profound apathy is often present. Children are often more seriously affected, the disease in them leading to deterioration of character

without any corresponding impairment of intellect. They are apt, therefore, to develop habits of lying, stealing and violence, which make it difficult to control them at home and lead not infrequently to the police court.

Insomnia at all ages is a common and distressing sequel. The patient is drowsy and apathetic during the day, but at night time becomes restless and agitated, often excited, and gets off to sleep only in the early morning.

Diagnosis. In cases of the common type beginning insidiously with drowsiness, low fever, and ocular palsies, this is comparatively easy, but may be a matter of extreme difficulty when the incidence of the infection is more widespread. The diagnosis of cerebral abscess has to be considered, and, with this possibility in view, the ears should be examined for signs of suppurative otitis. Cerebral tumours also, especially if situated in one of the silent areas of the brain, may produce signs resembling those of encephalitis lethargica, but in this case examination of the optic discs may clear up the diagnosis, papilloedema being seldom absent in cases of tumour, rarely if ever present in encephalitis.

Cases in which the illness is ushered in with meningeal symptoms may simulate meningococcal or tuberculous meningitis, but the neck stiffness is hardly ever so important a feature of encephalitis as in these illnesses. In the rare instances in which the onset is apoplectiform, the condition can hardly be differentiated from that caused by a cerebral hæmorrhage or thrombosis.

In the later stages, after the decline of pyrexia, the presence of signs of widespread involvement of the nervous system may suggest the possibility of syphilis, when the Wassermann reaction in blood and cerebro-spinal fluid will be of use in settling the point. Cytological and bacteriological examination of the cerebro-spinal fluid is always of value in making the differential diagnosis. In the later stages cases presenting the Parkinsonian syndrome have to be distinguished from paralysis agitans. Careful enquiry for a history of febrile illness, transient diplopia, or sudden lethargy or insomnia preceding the Parkinsonian symptoms, by months or years, may decide the diagnosis. In cases where such a history is lacking the age of the patient may settle the question, paralysis agitans being a disease of middle or late life, while encephalitis lethargica attacks young as well as old. When this method of distinction is not available the detection of anomalies of the pupillary reactions and ocular movements, especially a failure of convergence and of the pupils to contract on attempted convergence, may decide the diagnosis in favour of encephalitis lethargica.

Prognosis. The death rate appears to be about 20 per cent. if note is taken of the abortive cases. The notification returns show a considerably higher rate of mortality. The large majority of deaths occur within the first three weeks of the illness, and after this period the prognosis as regards life is good.

Signs of ill omen are a rising temperature (above 102.5°), deepening of stupor into coma, or noisy delirium with extensive muscular twitchings (the acute myoclonic form).

In the cases which recover the cranial nerve palsies as a rule clear up, relatively soon leaving, perhaps, inequality of the pupils with sluggish contraction in accommodation. Lethargy, weakness and slowness of movement may persist for many weeks and develop gradually into the clinical semblance of paralysis agitans.

Symptoms of the order already described as belonging to the late stage may continue to make their appearance for as long as two or three years after the onset, but it may be said as a rule that a patient who has recovered from the initial attack and has thereafter remained completely free from fresh symptoms for six months is unlikely to have further trouble.

Of the late symptoms the paralysis agitans group show a tendency to progress slowly; they eventually come to a standstill, and there may be a slight improvement, but the patient is left considerably disabled. The involuntary movements develop slowly (over a period of months) to their climax, and as gradually recede,

often with but slight residuum. The mental changes, both in adults and children, though there may be some remission, appear for the most part to be of a permanent nature.

Treatment. There is no specific treatment for the disease. Urotropin in full doses should be given in view of its possible antiseptic action, and symptoms should be attended to as they arise. In most cases the patient can be roused to take his food, which should be confined to a light and easily assimilable diet with plenty of fluids. Occasionally the stupor is so deep that tube feeding has to be resorted to, and this may also be rendered necessary by dysphagia, due to glosso-pharyngeal paralysis apart from stupor. The method of choice is by the nasal tube, through which an ample diet may be given in the shape of milk, beaten-up eggs, malt, and orange juice. The bladder should be watched carefully, since retention with overflow may occur, and if neglected lead to cystitis. In prolonged cases there is, as a rule, much emaciation, with probable development of bedsores, so that it is wise to have the patient upon a water-bed if the course of the illness appears likely to be protracted. For the insomnia, which is sometimes a distressing sequela, hot baths (for one hour before bedtime) and various drugs may be tried, of which the most useful are paraldehyde in full doses and the veronal compounds. For rigidity of the limbs after the acute stage has subsided passive movements should be carried out daily, preferably after a hot bath.

In view of the grave risk of a smouldering infection leading to further symptoms, convalescence should wherever possible be prolonged, and the patient advised not to resume his full round of activities for a period of six months after the progress of symptoms has ceased. During this period regular exercise should be prescribed for body and mind, but this should stop short of fatigue.

Drugs of the belladonna group are of considerable value in the treatment of the Parkinsonian group of symptoms of the later stages. The effect is to diminish rigidity and increase the possible range and rate of movement. Large doses are necessary, and much depends upon the amount the patient can take without toxic symptoms. The tincture of stramonium seems to be the most effective preparation, and in the case of an adult should be given in doses at first of ℥xv. t.d.s. p.c. in $\frac{1}{2}$ oz. of chloroform-water. After a few days the dose is increased to ℥xx., and thenceforward at similar intervals by increments of ℥v. until the limit is reached of the patient's tolerance. This is shown by complaint of weakness in accommodation, dryness of the mouth palpitation and tachycardia. Of these the first symptom is usually the earliest to appear, and may be overcome by giving a solution of eserine sulphate $\frac{1}{4}$ per cent., one drop to be instilled into each eye every morning. The dryness of the mouth may be relieved by acid drops. Thus the patient may be enabled to continue with the larger doses. An alternative plan is to add to the mixture pilocarpine nitrate in the proportion one-tenth of a grain to thirty minims of the tincture of stramonium. If as much as ℥xl. can be taken t.d.s. a great deal of relief may be obtained, so that a patient for instance who, without the drug is unable to feed or dress himself, is enabled with its aid to do so. Unfortunately the effect is apt to pass off with continued use, but may be prolonged by withdrawal of the drug during one week in every six, or on one day during the week, during which none of the belladonna derivatives should be given.

Prevention. The Ministry of Health makes the following recommendations (1924) :—

“ The other occupants of a house in which a case of encephalitis lethargica has occurred, or is being treated, may be assured that the disease is one of low infectivity, and that very slight risk is run by association with the patient. At the same time it is desirable that such association should be limited to what is necessary for proper care and nursing, and the patient should be well isolated in a separate room.

“School children in the affected household may be kept from school, as a precautionary measure, for three weeks after the isolation of the patient. There is no necessity to place restriction on the movements of other occupants, provided they are frequently examined and remain well. Those in contact with the case, however, may be advised to use antiseptic nasal sprays or douches and to gargle the throat with solutions such as those advised for influenza.

“For example, any of the following :—

- (1) One per cent. solution of peroxide of hydrogen.
- (2) A solution of permanganate of potash, 1 in 5,000, in 0·8 per cent. solution of chloride of sodium (common salt).
- (3) *Liquor sodæ chlorinatæ*, 0·5 per cent.

“These solutions can be used as ordinary throat gargles or snuffed up the nostrils, or applied by an efficient spray.

“Any persons in the infected household who suffer from sore throat or other symptoms suggesting an abortive attack should be treated from this point of view and isolated as far as possible until they have recovered.

“The sick room should be thoroughly cleansed and disinfected at the end of the illness.”

ABSCESS OF THE BRAIN

In the great majority of cases abscess can be shown to be the result of direct infection by pyogenic organisms. By far the commonest cause is suppurative otitis media. It may also follow infection of the frontal or ethmoidal air sinuses, and compound fractures of the skull. Indirect infection by way of the blood stream is rare, but may lead to the formation of a cerebral abscess in pyæmic conditions, and especially in cases of chronic suppuration within the chest, such as bronchiectasis or empyema. In these latter cases the cause is presumably the detachment of an infected thrombus which lodges in the brain.

The pathological appearances vary with the age of the abscess. The first stage is that of acute suppurative encephalitis. This may extend diffusely, and if so leads rapidly to a fatal issue. The abscess cavity is then found to be ragged, with purulent infiltration of the surrounding brain substance. As a rule, however, there is sufficient reaction on the part of the surrounding tissues to form a comparatively firm and smooth wall, which limits the spread of the infective process, and a chronic encapsuled abscess results. Abscesses arising from the middle ear are commonly situated either in the cerebellum or the temporal lobe. The cerebral abscess may be associated with an extra-dural abscess, or there may be adhesions between the dura and leptomeninges, showing the track of the infection, or as in many cases the meninges over the abscess may appear healthy with no evidence of the path of entry. The streptococcus is the organism most frequently found, but in the otitic cases the bacillus coli communis is sometimes met with, giving a characteristically foul odour to the pus. In the pyæmic cases the staphylococcus is sometimes responsible.

Symptoms. These depend partly upon the infective nature of the condition, partly upon the situation of the abscess. In those of otitic origin the initial symptoms are often slight and pass unnoticed in the course of a suppurative otitis media or mastoiditis. They consist of fever and headache, often associated with vomiting and drowsiness. If the suppurative process spreads unchecked these symptoms rapidly progress, the temperature remains high, signs of cerebellar or cerebral destruction appear, and the patient dies within a week or two. Much more frequently the abscess becomes encapsuled, the initial symptoms, which may have been slight, subside, and a chronic abscess results, whose symptoms depend almost entirely upon its situation. Thus the patient with a chronic cerebral abscess may continue at his work for weeks or months with few symptoms and without appearing to be seriously ill. Headache of a bursting or splitting character is the most constant symptom of the early stages of a chronic abscess,

but may be intermittent. The important signs of a cerebellar abscess on either side are nystagmus on looking towards the side of the lesion, inco-ordination of the limbs on the same side as shown, especially in the finger-nose-finger test, and a tendency to stagger to the same side in walking. In the case of a left temporal abscess in a right-handed person aphasia is the most important localising sign, and takes the form of verbal amnesia, so that careful testing will reveal the patient occasionally at a loss for the correct word in attempting to name a series of objects presented to him.

Further signs common to an abscess in either temporal lobe are a weakness of the lower part of the face on the opposite side, and a defect in the visual field. The latter commonly takes the form of an upper quadrantic defect from involvement of the inferior bundle of the optic radiation as it runs through the posterior part of the temporal lobe. As the abscess increases in size the signs of increased intracranial pressure, headache, vomiting, drowsiness and slowing of the pulse, become more apparent, and papilloedema develops. The temperature, as a rule, is normal or sub-normal.

The cerebro-spinal fluid is under increased pressure, and commonly shows a moderate increase of cells, consisting mainly of lymphocytes with a small proportion of polymorphs, and the protein is also increased. Any large number of polymorphs in the fluid is suggestive of an abscess leaking either into the ventricle or into the subarachnoid space.

Diagnosis. The development of cerebral symptoms in the course of an otitis media, especially if this is complicated by mastoid infection, will always raise the question of abscess. This, however, has to be distinguished from other complications, such as lateral sinus thrombosis, extradural abscess and meningitis, which may occur separately or may coincide with the presence of a cerebral abscess. A careful search for the signs already enumerated of cerebellar and temporal lobe disturbance may decide the question, but the right-sided temporal abscess in particular may give rise to few signs. Examination of the spinal fluid may help, but it should be remembered that lumbar puncture is not without risk of spreading the infection. The fluid, therefore, should be examined at once and an operation performed without further delay if the evidence is positive. The chronic abscess may present great difficulties in diagnosis. Whenever there is persistent complaint of severe headache in a person with a discharging ear the possibility of abscess should be considered and the patient examined in the manner already described. It must be remembered, however, that chronic otorrhœa is common and may exist together with cerebral syphilis or cerebral tumour.

Prognosis. Many cases have been cured by evacuation of the abscess; without the help of surgery recovery cannot be expected.

Treatment. Where an abscess can with reasonable certainty be recognised, and its locality accurately determined, the attempt to evacuate the pus should be made.

Apart from surgical interference, the treatment of abscess of the brain must be purely symptomatic; the relief of pain may be attempted by local anodynes, by ice to the head, and by aspirin or morphia.

CEREBRAL CONTUSION

As a result of violence directly or indirectly applied to the head the cerebral substance may suffer laceration and bruising. Such damage to the brain, although commonly associated with evidence of external injury to the scalp or cranium, may occur without this, and in any case, apart from such complications as an infected compound fracture or arterial hæmorrhage, the important symptoms are those due to the cerebral rather than the cranial damage.

Pathology. The anatomical changes underlying the symptoms to be described may be inferred from inspection of the brain in fatal cases. Rupture

of the capillaries and small veins is the essential feature of the injury, with resultant extravasation of blood. This may take the form of multiple petechial hæmorrhages scattered throughout the brain, or of larger extravasations commonly related to the point of impact in the case of a direct injury or to the point of *contrecoup*. In these larger areas of injury the brain substance is frequently torn asunder by the escaping blood. The anterior poles and under surface of the temporal and frontal lobes are especially liable to injury from indirect violence, probably as was first pointed out by Hilton, because the water-bed of cerebrospinal fluid is shallow in these situations, and the irregularities of the cerebral cortex more closely applied to similar contours in the bone.

Symptoms. If the injury has been a severe one there will probably be a history of concussion—that is total loss of consciousness immediately following the accident. The symptoms of concussion being due to a transient cerebral anæmia without structural damage are themselves transient. The phase of cerebral anæmia may be followed by one of œdema, with consequent headache, vomiting and drowsiness, but these symptoms in a case of simple concussion, uncomplicated by structural damage, should have disappeared at the end of twenty-four hours. It follows that any symptoms of cerebral disorder persisting after this time must be attributed to organic damage. This damage—apart from the possibilities of infection and meningeal hæmorrhage—will consist of cerebral contusion sustained at the moment of injury.

The symptoms of cerebral contusion vary from a condition of persistent stupor or delirium at one extreme to occasional headaches at the other. For purposes of clinical description it is therefore of advantage to distinguish between a major and a minor degree of cerebral contusion, on the understanding that the line of division is arbitrary. The most convenient means of distinction is to include in the category of major contusion all cases showing clouding of consciousness or stupor, the remainder constituting the group of minor contusions.

Major Contusion. The injury will almost always have been of such a nature and degree as to have caused immediate concussion. Following this the patient partially regains his senses, but instead of making that rapid and complete recovery to the normal state which characterises a simple concussion, is found at the end of twenty-four hours to show some degree of mental clouding. In a severe case this will amount to a state of stupor in which the patient is commonly said to be unconscious. He will, however, respond to vigorous stimulation, usually with a show of resentment, and is apt, especially at night-time, to be noisy and violent, with hallucinations of vision and hearing. The temperature and pulse rate are commonly raised. This condition, known as cerebral irritation or traumatic delirium, betokens extensive cerebral contusion. In milder instances the clouding of consciousness may not be apparent unless carefully enquired for. The patient may behave normally but is imperfectly aware of his surroundings, his memory for the events of the day is defective and he is subsequently found to have little or no recollection of this phase of his illness. Physical signs of local cerebral damage are not an essential feature of the clinical picture, but in the early stages of a severe case the plantar responses are commonly extensor. Lumbar puncture gives a fluid which is often blood-stained from the rupture of superficial vessels, and sometimes shows an increased pressure. In the severest cases death may occur during the first week either from the exhaustion of delirium or involvement of the medullary centres. The general tendency is towards recovery, which is, however, often incomplete. Mental deterioration of a degree necessitating institutional care is extremely uncommon (*vide* "Organic reaction type" of mental disease, p. 769), but lesser changes are often apparent. These take the form of defective memory and concentration, loss of emotional control, and alterations in the personality. Pre-existing trends of a psychotic or psychoneurotic nature may be accentuated, and there is a general defect of inhibition. Other symptoms of the recovery stage are headache and

giddiness of the type presently to be described as characterising minor contusion. Under proper conditions improvement may continue for a year or eighteen months, but analysis of the end results in a series of head injuries collected by the writer showed that not more than one-third of those who had suffered major contusion had returned to full work one year after the accident.

The **treatment** of major cerebral contusion in the early stages consists of rest. Careful nursing is essential. Morphia, or morphia and hyoscine, may be necessary at first to control excitement. Subsequently chloral and bromide and paraldehyde, either by the mouth or in double doses by the rectum, are best employed, the object being to control restlessness as far as possible without inducing stupor. Feeding may be regulated by the patient's tastes and the exigencies of the moment. Alcohol should be withheld. Lumbar puncture should be performed and the pressure of the cerebro-spinal fluid measured with a manometer. If it is raised enough fluid should be withdrawn to bring the pressure down to normal (120 mm. of water), the patient should be propped up in the Fowler position, and mag. sulph. should be given by the mouth to the point of looseness of the bowels, or by the rectum in the form of a solution containing ℥iii of mag. sulph. in ℥vi. of water. In many cases, however, the pressure is found to be normal; in these no cerebro-spinal fluid should be withdrawn, and dehydration with mag. sulph. is unnecessary.

In the convalescent stage the treatment is the same as for minor contusion.

Minor Contusion. Symptoms of this order may follow upon those of concussion or may develop without any such prelude after an injury which at the time has seemed of no moment. There is quite commonly an interval of a day or two before the symptoms develop, during which the patient regards himself as completely recovered from his accident. The main complaints are of headache, giddiness and failure of the higher mental functions, expressed as loss of confidence, nervousness and difficulty in concentration.

The headache may be of two kinds. That which is most characteristic is an intermittent throbbing and bursting pain provoked or aggravated by coughing, stooping or straining, and by any unusual physical or mental effort. It is often referred to the site of the injury or the point of *contre coup*, but may be frontal or generalised. In response to questioning the patient will usually admit a relation to posture, the headache being as a rule worst when he is in the horizontal position. This type of headache resembles that met with in known cases of intracranial pressure and is probably due to this cause. The other variety is constantly associated with some or other of the mental symptoms to be described. It is described in terms of discomfort rather than pain—a sense of pressure, heat or numbness enveloping the head—is continuous rather than intermittent, and is aggravated by mental tension or distress.

The mental symptoms comprise slowing of the intellectual processes, which is not only complained of by the patient, but is noticeable in his speech and actions: indecision, timidity, and defective emotional control.

The giddiness is usually described as a general sense of unsteadiness with fear of falling, transient and provoked by stooping or quick movement of the head.

This triad of symptoms, when they are present together, constitutes an easily recognised clinical picture. Any one of them, however, may predominate. Physical signs are usually lacking, although a careful neurological examination will occasionally reveal an unsuspected extensor plantar response, absent abdominal reflex or nystagmus as evidence of focal damage.

With proper management most cases of minor contusion make complete recoveries. In the minority some of the symptoms continue indefinitely, the liability to headaches of the hypertension variety being the most persistent.

Prolonged rest and a properly graduated convalescence are the essential points in the **treatment** of minor contusion. The patient should at first be put to bed. The sitting posture is that which in theory and practice is most likely to relieve

intracranial pressure, but the patient should be encouraged to find the optimum position for himself.

Bright light and noise should be excluded as far as possible, visitors forbidden, and absolute quiet enjoined. Light reading may be allowed and tobacco is permissible, but alcohol should be prohibited. A mixture, containing pot. brom. gr. x.—xv. t.d.s., should be given to induce relaxation, and the patient encouraged to doze. Aspirin and phenacetin may be given at need for headache, and at night medinal grs. v.—x., if necessary, for insomnia. The bowels should be opened to the point of looseness every morning with the requisite dose of mag. sulph. This *régime* should be continued until the patient has been free from headache for three or four days. He may then be allowed, step by step, to take more liberties, commencing with permission to walk to lavatory and bathroom, and proceeding at two-day intervals to more and more physical and mental activity. The recurrence of symptoms such as headache or insomnia should be the signal for retiring a step and making a fresh start on the road to convalescence. It is particularly desirable that the final stage be well managed and the patient have an opportunity, in the shape of a holiday, of testing his capacity for mental and physical endurance before returning to work. It is impossible in the early stages to forecast the duration of the illness, which must depend upon the results of treatment.

Differential Diagnosis. The symptoms of cerebral contusion in its later stages or minor degree may closely resemble those of an anxiety neurosis. Hence the term “traumatic neurasthenia,” which is often used to cover all conditions of minor mental disorder following upon injury without discrimination between the organic and the psychoneurotic elements. The distinction, however, is important, both from the therapeutic and the medico-legal aspects. A neurosis—arising usually out of the desire to exploit illness for purposes of compensation—may follow an accident to the head as well as to any other part of the body. It needs to be treated by means of psycho-therapy, and may be assessed as a condition which is completely recoverable. The mental symptoms of contusion depending upon organic cerebral damage, besides needing different treatment, carry the possibility of a permanent impairment of wage-earning capacity. In the absence of physical signs the differential diagnosis may be very difficult.

Points in favour of cerebral contusion are: *objective* difficulty in concentration, defect of memory and slowing of the intellectual processes; the association with other contusion symptoms such as headache of the hypertension variety and vertigo; and a history of prolonged clouding of consciousness following the injury. The most difficult cases are those in which the symptoms of an anxiety neurosis—a not unnatural development in a disabled workman—are added to those of true cerebral contusion.

INFANTILE CEREBRAL DIPLEGIA

(*Infantile Spastic Paraplegia, Diplegia Spastica, Congenital Spastic Paraplegia, Birth Palsy*)

This title includes all cases of bilateral spastic weakness of the extremities, of cerebral origin, occurring in infancy or early childhood.

These cases may be further divided into two groups according to their pathological and clinical features (6).

Group I. comprises those cases in which the symptoms are due to lesions of both cerebral hemispheres resulting from injury or infection, at or after birth. Of such causes the commonest are meningeal or cerebral hæmorrhages as the result of birth injury, and acute encephalitis (*see* p. 704).

The brain in such instances provides post-mortem evidence of injury or inflammation in the shape of meningeal scarring and cyst formation in the traumatic cases, and perivascular scarring in those of infective origin.

Clinically in many cases no definite history of injury or infection may be obtained, but a series of convulsions occurring shortly after birth is suggestive of meningeal hæmorrhage, or a history may be elicited of an acute febrile illness in infancy.

The symptoms are as a rule asymmetrical, one limb or one side of the body being more involved than the other. Actually the paralysis often escapes notice until the child proves backward in sitting up, walking and talking.

The damage in these cases is of an irreparable nature, but a great deal may be done for these children by means of carefully planned remedial exercises and drill. There is almost always some degree of mental impairment, which is irremediable. Nevertheless these children are much more educable than may appear at first sight and will usually repay patient instruction.

Group II. comprises the majority of cases of cerebral diplegia, and consists of cases in which as the result of some obscure cause acting as a rule in utero, but sometimes after birth, the development of the cortical cells is arrested or retarded.

In a severe case of this kind the brain is small and atrophic, with wide sulci and wrinkled convolutions, and is sometimes compared to a walnut kernel. Microscopic examination reveals a diminution in the numbers of the cortical nerve cells with secondary overgrowth of neuroglia. The process is symmetrical in the two hemispheres and frequently includes the cerebellum. The optic nerves also are frequently degenerated.

Clinically these cases are distinguished by the remarkable symmetry of the spasticity and weakness. Nothing may be noticed at birth, although a history is often obtained of premature, sluggish, or precipitate labour, which is possibly due to the same cause affecting the reproductive mechanism of the mother as is responsible for the disease in the child. After birth the child may suck feebly, but often nothing is noticed until he proves backward in sitting up and slow at learning to walk, owing to the stiffness of the lower limbs. Ultimately the condition is much like that seen in the spastic paraplegia of adults. The limbs are extended and rigid with increased tendon jerks and persistent extensor plantar responses. Sometimes spasm of the adductors is extreme and the legs are crossed over one another, in spite of which the child manages to walk—*crossed leg progression*. The arms are never as rigid as the legs, and may escape entirely. The picture may be complicated by the addition of cerebellar ataxia and nystagmus, and optic atrophy is of frequent occurrence. Some degree of mental impairment is usually present.

In the cases which are of congenital origin (and these are in the majority), although the development of some nerve cells would seem to have been arrested in other cells it is merely retarded, and as the result of suitable treatment by means of remedial exercises and patient education considerable improvement may be expected.

Treatment. In cases of both groups this is the same, and must consist of regular exercises and drill with suitable educative measures. Deformities must be treated by manipulation, splinting, and tenotomies when necessary. A small proportion of cases of Group II. are of syphilitic origin and should be treated accordingly.

Amaurotic Family Idiocy (Tay-Sachs' Disease). This is a familial disease of infancy affecting chiefly the Jewish race and depending upon a progressive degeneration of the nerve cells in the retina and throughout the nervous system. The affected cells become swollen, subsequently degenerate, and are finally absorbed. The symptoms, as a rule, commence within the first year of life and consist of mental enfeeblement, convulsions, and spastic weakness, together with failing vision. The ophthalmoscopic picture is characteristic. The retinal degeneration is maximal at the macula and the choroid showing through it in this region appears as a cherry-red spot. The optic discs show primary atrophy.

The disease is steadily progressive and ends fatally as a rule within a year of the onset. In the terminal stages the paralysed limbs become flaccid.

Cerebro-Macular Degeneration (*Juvenile Form of Tay-Sachs' Disease, Vogt-Spielmeyer Disease*). This disease resembles amaurotic family idiocy in having a familial incidence and depending upon a simultaneous degeneration of the nerve cells in the brain and retina. It is, however, commonly encountered among non-Jewish people, and begins in childhood rather than infancy. The ophthalmoscopic appearance also differs from that of amaurotic idiocy. The earliest change is a white circle with red margin in the macular area. Subsequently in the same area minute white spots and specks of pigment appear, giving a pepper-and-salt appearance. The optic discs show a waxy pallor. The retinal degeneration ultimately becomes widespread. Clinically there is progressive failure of vision with mental deterioration and epileptic attacks, and the physical signs of cerebral and cerebellar disease. The progress of the disease is slower than in amaurotic idiocy, but death usually occurs before the age of fifteen.

The age of onset, as well as the ophthalmoscopic appearance, serves to distinguish this disease from amaurotic family idiocy. From infantile cerebral diplegia, as already described, it may be distinguished by the progressive nature of the symptoms and the retinal involvement.

Schilder's Encephalitis (*Encephalitis Periaxialis Diffusa*). This disease was first described by Schilder in 1912, although an unpublished case had been recognised by Collier at the National Hospital, Queen Square, in 1902. It would appear to be at least as common as the two diseases just described, and to account for some proportion of the cases of progressive diplegia seen in children and young adults. It is characterised pathologically by a degeneration of the white matter in the cerebral hemispheres, the sub-cortical or arcuate fibres alone being spared. This may commence in any part of the brain and is usually symmetrical. The optic nerves are not infrequently involved. The cause of the degeneration is obscure. A few cases have been recorded of familial incidence. The age of onset varies, but appears usually to be in infancy or childhood. The symptoms depend upon the parts of the brain chiefly affected. Involvement of the occipital lobes has led in several cases to the gradual development of blindness with normally reacting pupils and normal fundi. Bilateral involvement of the temporal lobes may lead to progressive deafness, of the parietal lobes to sensory loss, and of the pyramidal fibres to a double hemiplegia. Mental deterioration is a part of the clinical picture, epileptic attacks may occur, and primary optic atrophy is not uncommon. The rate of progress is extremely variable, and may be so even within the same family. Thus the writer has recorded the instance of a boy of six who died within a year of the onset. A sister, who developed her first symptoms in infancy, is blind and quadriplegic, but still alive at the age of twenty-two. A brother showed primary optic atrophy, epilepsy and mental deterioration from the age of four, but his symptoms remained stationary for six years and then progressed to a fatal issue at fourteen.

CEREBELLAR ATROPHY

Degenerative changes may occur in the cerebellum in several of the diseases which have already been described, as, for instance, in arteriosclerotic softening, cerebro-macular degeneration and Schilder's disease. In these instances, however, the cerebellar lesions are associated with cerebral disease. There are also certain maladies of a degenerative character in which the cerebellum is primarily or solely affected. Of these the most clearly distinguished are the following.

Marie's Hereditary Cerebellar Ataxia. In this disease, which is usually but not always inherited, the symptoms commonly commence in early adult life and are gradually progressive. They comprise inco-ordination of the upper and lower limbs, unsteadiness of gait, nystagmus, slurred speech, and in the majority of cases optic atrophy. The disease may be distinguished from Friedreich's ataxia

by the preservation of the tendon jerks, the flexor plantar responses, the optic atrophy and late age of onset. Transitional forms between the two diseases are not infrequently seen, and it is probable that they belong to the same group.

Senile Cerebellar Atrophy. This is a disease of late middle life or old age characterised pathologically by degeneration of the cerebellar cortex. This affects particularly the middle lobe. The Purkinje cells and their axons degenerate and are absorbed, the other cortical nerve cells being less affected.

Clinically, the malady begins with unsteadiness of the gait, which is of the cerebellar type, reeling and titubant. At this stage there is often little else to be made out. As the disease gradually progresses inco-ordination of the lower limbs is demonstrable in the heel-knee test. The upper limbs are involved later and to a less extent. The speech in the later stages is slurred and explosive, but nystagmus is an uncommon feature.

The diagnosis in the early stages has to be made from hysteria. In the later stages the progressive cerebellar symptoms, together with the age of the patient, form a characteristic clinical picture.

HEPATO-LENTICULAR DEGENERATION

This is a rare disease in which progressive degenerative changes in the brain, and especially in the lenticular nuclei, are associated with multi-lobular cirrhosis of the liver. In about half the recorded cases the disease has been familial. Nothing is at present known as to its cause, but it is of interest that chronic manganese poisoning causes both cirrhosis of the liver and degenerative changes in the corpus striatum. The onset is as a rule in childhood or adolescence. The symptoms of cerebral disease take the form of tremor and rigidity of the limbs which are of the type encountered in paralysis agitans. Together with this there is slurring of the speech, and some degree of mental deterioration. In some cases, which probably belong to the same group, the motor symptoms may take a different form—that of continuous writhing movements of the limbs and trunk (torsion spasm). The symptoms of hepatic affection are inconstant, but enlargement of the liver, jaundice, or ascites may occur in the course of the nervous illness or may sometimes precede it. The disease is progressive and fatal, but its course may be acute or chronic, varying from a few months to several years. Treatment is purely symptomatic. The diagnosis has to be made from the late stage of encephalitis lethargica, a history of febrile illness with diplopia and abnormalities of the pupils or ocular movements being the main points in favour of the latter diagnosis.

PARALYSIS AGITANS

(Shaking Palsy, Parkinson's Disease)

This disease consists, in its fully developed form, of rhythmical contractions of the muscles of the limbs associated with weakness and rigidity.

Ætiology. It is a disease of advanced life, rarely occurring before the age of forty-five years, but, on the other hand, not often commencing after the age of sixty-five. It occurs in men twice as often as in women. It cannot be traced to any definite cause.

Pathology. Recent researches have indicated that the symptoms of paralysis agitans may be produced by lesions of certain areas of the brain, and that these lesions may be the result of various pathological processes. The exact site of the areas affected is a little uncertain. On the one hand, symptoms in many ways resembling those of paralysis agitans have been observed in association with progressive degeneration of the lenticular nuclei (*see above*), and in typical cases of juvenile paralysis agitans Ramsay Hunt claims to have found atrophy of the motor cells in the globus pallidus. Many Continental observers, however, point to changes in the substantia nigra of the mid-brain as

being the most important pathological features. The truth probably is that we are dealing with an *affection of a system of extra-pyramidal motor fibres* in which cell stations and neuronic pathways both in the corpus striatum and the mid-brain play an important part. As to the *nature* of the pathological process, there can be no doubt that the virus of encephalitis lethargica may be responsible in a certain number of cases, especially those occurring in young people (see p. 707). In hepato-lenticular degeneration the association with cirrhosis of the liver suggests some unknown toxic factor as the primary cause. The common form of the disease beginning in old people may possibly be due to arteriosclerotic changes in the brain, or to a system degeneration akin to that seen in progressive muscular atrophy. But of this at present we have no certain knowledge.

Symptoms. In some cases the first symptom is the tremor, after which the disease is named; in others rigidity is observed before any tremor has occurred; but ultimately they are both present.

Tremor. In the former case, it is noticed that one hand and arm are the subjects of a tremulous movement, due to rhythmical contractions of antagonistic muscles. The movement is most marked in the hand; the fingers are generally flexed, with the thumb resting against the forefinger; and the constant slight flexion and extension of the fingers and thumb produces a movement like that required for rolling pills. Similar slight movements of flexion and extension occur at the wrist and elbow joints. After the tremor has existed for some time in one arm it generally spreads to the leg of the same side, and then in succession to the arm and leg of the opposite side. The trunk may also be affected, though it is not always easy to say how much the tremor is due to the movements in the legs; and, finally, in some cases, there is a slight movement of the head. Occasionally even the muscles of the jaw and tongue, but very rarely those of the face, are affected. These movements vary in extent; in rapidity they range between $4\frac{1}{2}$ and 7 to the second. As a rule the movements continue even during rest; thus, if the patient sits with the arm resting on the knee, both the leg and the hand and arm will continue to tremble. In early cases, however, support may check the tremor for a time, and in advanced cases, with the rigidity to be presently described, the tremor may only occur on movement. By voluntary efforts fixing the limb the tremor may also for a time be stopped, and it ceases during sleep.

Rigidity. This differs from that met with in spastic conditions following pyramidal lesions in that the rigidity is more evenly spread, affecting both extensor and flexor groups, and more evenly maintained in opposition to passive movements. When it is the first symptom it may be observed that the thumb and forefinger are rigid without any tremor: rigidity extends to other parts, and tremor is developed later. In a case which has begun with tremor in one limb, the rigidity may appear first in another limb, and be followed by trembling. The muscular weakness is shown by deficient power of grasp, and fatigue on exertion, so that in the early stages, for instance, a man may find difficulty in buttoning up his collar, and a woman in doing her hair. The rigidity imposes a characteristic posture, which is most marked when the patient is standing. The head and body are bent forwards; the elbows are flexed nearly to a right angle, and stand out a little from the side; the hands are in the position above described; and the legs are slightly bent at the knees. The gait in fully developed cases is very peculiar: the patient rises from his seat slowly and with apparent difficulty, and his first steps are hesitating; but soon his movements become quicker and quicker, he seems with each step to be trying to prevent a fall, and ultimately, unless stopped, he may actually fall forward to the ground. Some patients when gently pushed backwards are unable to stop themselves, and continue to walk backwards until they meet an obstacle or fall. The terms *festination* and *propulsion* have been used to describe the forward tendency; *retropulsion* and *retrogression*, the backward movement. The face has a characteristic

and fixed expression, due to the rigid condition of the facial muscles (Parkinsonian mask), and this may be a comparatively early symptom of the disease. Speech may be similarly slow at first, and afterwards rapid; it is often high-pitched or thick and feeble. Otherwise all movements tend to be slow on account of the rigidity; for instance, the patients turn with difficulty. The muscles are not hypertrophied by their excessive action, and only in late cases with long-continued rigidity do they present some atrophy. The reflexes are normal. Some subjective sensations are often experienced, such as dull aching pains, sense of fatigue, or a feeling of restlessness, and especially a sense of great heat, which is often accompanied by free perspiration; while a flush on the cheek of the patient shows vasomotor weakness.

Diagnosis. There is but little difficulty in recognising *paralysis agitans* when tremor is present. *Senile tremor* is distinguished from it by the constant trembling of the head. The movements also are finer, both arms are often involved together, and there is no rigidity; it comes on later in life. The tremor of disseminated sclerosis is of the intentional type, is not accompanied by rigidity and is associated with other physical signs. Especially if the symptoms are confined to the limbs of one side, there is a resemblance to a hemiplegia of pyramidal origin, but this may be excluded by the absence of alterations in the reflexes, and by the presence of the mask-like expression, which even when present in slight degree is often characteristic. Cases of slight double hemiplegia may be distinguished by the bulbar symptoms and mental changes, as well as by minor alterations in the reflexes.

Prognosis. The disease is chronic and progressive, yet its course may be very slow, two or three years perhaps elapsing between the affection of one and another limb. It is fatal only through bedsores or exhaustion in the extreme cases; intercurrent disease—*e.g.* of the lungs—terminates others.

Treatment. There is no curative treatment for the disease. The tremor may be controlled to some extent by sedatives such as bromide and luminal. The rigidity is often amenable in some degree to drugs of the belladonna group, of which the tincture of stramonium is usually the best. This should be given in a dose of 20 minims thrice daily, and this dose should be increased by 5 minims daily up to the limit of the patient's tolerance as indicated by dryness of the mouth or paralysis of visual accommodation. The patient who can take 40 to 60 minims thrice daily frequently obtains great relief. For those who cannot tolerate such doses without it, the addition of pilocarpine nitrate to the medicine in the proportion of one-tenth of a grain to 20 minims of the tincture of stramonium may be of value.

When once the optimum dosage of stramonium has been reached it should be continued, but with regular and continued use its good effect is frequently lost. This is less likely to occur if the drug is periodically omitted, *e.g.* during one week in six. Hyoscine hydrobromide by hypodermic injection in a dose of $\frac{1}{200}$ to $\frac{1}{100}$ a grain may be a useful adjuvant to the stramonium for special purposes, such as enabling the patient to fulfil some business or social engagement, or to enable him to achieve the physical relaxation necessary for going to sleep.

A great deal is to be gained if the patient can adopt a plan of living which will enable him to have assistance in dressing, undressing and the like, so that he may conserve his energies for other occupations. Fatigue has always a bad effect. Massage and passive movements have their value both in improving muscular function and in relieving the sense of stiffness which is often a source of great discomfort. In the case of a patient severely affected by the disease, stretching movements of the limbs with an alteration of the position of the body, carried out at regular intervals of half an hour by nurse or relative, may give much relief. The patient may be encouraged to take walking exercise with assistance. Travelling by car or omnibus often gives a sense of physical comfort probably due to the frequent slight changes of position which are possibly induced.

TUMOURS OF THE BRAIN

Intracranial neoplasms (including the infective granulomas) are of comparatively frequent occurrence among diseases of the brain. In the early stages of their growth they may give rise either to no symptoms at all, or to signs which require the most careful investigation by the physician before a successful diagnosis can be made. It is in these early stages, however, that surgical operation offers most chance of alleviation or cure. In the later stages the symptoms produced are as a rule easy of recognition, but the outlook from the point of view of surgical treatment is proportionately less hopeful.

Ætiology. Syphilis and tubercle account for the granulomas. In a certain number of cases of tumour there is a history of preceding head injury, but the causal connection is doubtful. Hydatid cysts and cysticercus occasionally play the part of cerebral tumours.

Morbid Anatomy. *Tuberculomas* account for a small proportion of intracranial tumours, and in Cushing's series of 2,000 verified cases amounted to less than 2 per cent. They are rarely met with except in children or adolescents, and are three times more common below than above the tentorium. They consist of globular masses in the cerebral substance, ranging from $\frac{1}{2}$ inch to 2 or 3 inches in diameter. These masses contain an inner core of yellow caseous material bounded by an outer narrow zone of a pinkish-grey colour and dense consistency. They can be easily detached from their bed. Microscopical examination reveals the presence of tubercle bacilli in sections through the wall of the granuloma, but the characteristic giant cell systems are frequently lacking. The surgical removal of a tuberculoma is almost always followed by death from tuberculous meningitis.

Circumscribed *gummas* are relatively uncommon—less than 1 per cent. of all intracranial tumours. They always grow in connection with the membranes, and are therefore commonly situated upon the surface of the brain. They may, however, be found in one of the central parts growing from a deep fold of the pia mater. They tend either to break down and become caseous in the centre, or to take the form of firm fibrous masses.

Hydatid cysts and the *cysticercus cellulosæ* are rarities which need not be described in detail. Hydatid cysts may attain to a considerable size and produce the signs of a large brain tumour. Those of the *cysticercus cellulosæ* are usually small and multiple, and, besides being found in the cerebral substance, may lie free in the ventricles.

Glioma. Of true intracranial neoplasms the commonest are the *gliomas*, which amount to more than 40 per cent. of the total. It has long been recognised that these tumours vary in their rate of growth, histological appearance, age incidence, and favourite situation, and several attempts have been made recently at a precise classification which will take into account all these features. The mature neuroglia contains three main types of cell derived from the ectoderm of the primitive neural tube. These are the *ependyma* cells which line the ventricles and central canal of the spinal cord, the *astrocytes* which constitute the main framework of brain and spinal cord, and the *oligodendroglia*, consisting of small round cells occurring in great numbers between the nerve fibres and around the nerve cells, which may play a part in the nutrition of myelin. In addition to these ectodermal derivatives there are the cells of the *microglia*, which are mesodermal in origin and perform the function of phagocytes. These do not give rise to tumours, but are mentioned here in order that a clear account of the neuroglial system may be presented. The ependyma cells, astrocytes, and oligodendroglia are derived in the embryo from more primitive types of cell known as *spongioblasts* and *medulloblasts*. Tumours of all these types of cell are encountered and many of intermediate character. As in the case of new growths generally those in which the type of cell is embryonic are the most rapidly growing and invasive, and those in which the cells are well differentiated are least so.

Although the gliomas are malignant tumours in the sense that they are non-encapsulated and invasive, they do not penetrate the dura mater, nor do they give rise to metastases outside the central nervous system. The *spongioblastoma* is one of the commonest varieties of glioma, and is characteristically a tumour of middle life occurring in the cerebral hemispheres or corpus callosum. These tumours appear to the naked eye as reddish, fleshy masses, with a fairly well-defined margin. They are highly vascular and frequently contain hæmorrhages, cysts and areas of necrosis. They are of rapid growth and little amenable to surgery. Microscopically they consist of relatively undifferentiated round or oval cells with no special arrangement.

The *medulloblastoma*, again composed of relatively undifferentiated cells which are round and may be arranged in rosettes, is essentially a tumour which develops in the first decade of life and is situated in the cerebellum or roof of the fourth ventricle. In Cushing's series it accounted for 10 per cent. of all verified gliomas. Like the spongioblastoma, it is vascular, of rapid growth and irremovable. Alone of the gliomas it tends to invade the pia-arachnoid and may seed itself throughout the subarachnoid space.

The *ependymoma* is a rare type of glioma, which again is seldom found except in the roof of the fourth ventricle. It is usually found in children or young adults, may be of slow growth and is capable of removal. Its situation, however, renders the operation dangerous, and Cushing's series show a 31·3 per cent. case mortality when radical extirpation is attempted.

The *astrocytoma* is a common tumour, occurring with about the same frequency as the spongioblastoma, and these two tumours together amount to 60 per cent. of all gliomas. The astrocytoma to the naked eye is a white infiltrating tumour of dense consistency. It occurs both in the cerebrum and cerebellum. In the former situation it is found in adults. In the cerebellum it is most characteristically a tumour of childhood and early adolescence, and frequently takes the form of a cyst containing a mural nodule of growth. It is a slow-growing tumour, and in the cerebellum especially lends itself to surgical removal, the case mortality for the cerebellar operation in Cushing's most recent series being 3·4 per cent.

The *oligodendroglioma* is a rare tumour of slow growth and with a marked tendency to calcification which is found in the cerebral hemisphere in adults. It has frequently been removed with success.

Meningioma or Dural Endothelioma. After the glioma the commonest tumour is the so-called *meningioma* or *dural endothelioma* (13·4 per cent. of all tumours in Cushing's series). These tumours may occur at any age, but are most commonly discovered giving rise to symptoms between the ages of thirty and forty. They are rarely met with below the tentorium. They arise apparently from arachnoid cells on the inner surface of the dura mater, and are essentially slow-growing encapsulated tumours of innocent type. They vary in size from that of a pea to a tangerine orange, are roughly spherical in shape, nodular, and of moderately firm consistency. They may have a wide connection with the dura mater or retain their attachment to it by a comparatively narrow stalk. They occur naturally upon the surface of the brain, which is compressed by the tumour, but a growth arising from the falx cerebri may so bury itself in the hemisphere from its mesial aspect as to appear as a subcortical mass beneath the lateral surface. At the point of attachment to the dura these tumours may become calcified or even ossified, or they may grow outwards, eroding the bones of the skull. They are occasionally multiple, and may be associated with multiple tumours of the nerve roots. Microscopically they consist of densely packed cells of a spindle shape, with large oval nuclei, which tend to be arranged in whorls and are supported by a connective tissue stroma. The centres of the whorls frequently undergo hyaline degeneration and calcification, and are then called psammoma bodies. Tumours of similar type may arise from the arachnoid membrane. The meningiomas obviously lend

obstruction between the source of secretion of the cerebro-spinal fluid in the lateral ventricles and the site of its absorption. The result is a *secondary internal hydrocephalus*, the distension being confined to the ventricle on the side opposite to the tumour, which is probably not occluded. There ensues a rapid further increase of intracranial pressure, wedging the pressure cone and the medulla firmly into the foramen magnum, and death follows from anæmia of the respiratory centres.

As regards their general effects, tumours situated in the posterior division of the cranial cavity—*subtentorial tumours*—may be divided into those growing from *without* the cerebellum, pons and medulla, and those growing *within* the cerebellum, pons and medulla.

Extra-cerebellar tumours are usually of slow growth, and have a certain amount of room in the lateral recess in which to expand. It is therefore only in their later stages that they cause a rise of tension in the posterior fossa. This is followed by the formation of a pressure cone from squeezing of the cerebellum into the foramen magnum, and in the manner already described secondary internal hydrocephalus is set up. In this case, however, *both* lateral ventricles are patent and become equally distended from accumulated pressure of cerebro-spinal fluid; the cerebral sulci become obliterated, the gyri flattened, and the pressure being transmitted along the optic nerves causes papilloedema.

Intra-cerebellar tumours are usually of more rapid progress, and the increase of pressure caused by them results in the early formation of a pressure cone and the rapid establishment of the conditions leading to secondary internal hydrocephalus, as described above, with general rise of intracranial tension.

Gliomas of the brain-stem will cause increased intracranial pressure early or late in proportion to the degree in which they cause obstruction to the outflow of fluid from the ventricular system. A large infiltrating tumour of the pons may be fatal without ever giving rise to internal hydrocephalus, while, on the other hand, a minute ependymoma of the iter, causing little or no local destruction, may, owing to its situation, cause a rapidly fatal increase of intracranial pressure. Tumours situated in the interpeduncular region, though compressing the structures in their immediate neighbourhood, may cause little or no increase of intracranial pressure.

General Symptoms. These are the symptoms of increased intracranial pressure, which, as has been shown in the preceding section, may develop relatively early in some cases, late in others—or may be absent to the end. They are symptoms, therefore, whose absence cannot exclude the diagnosis of cerebral tumour, though their presence may afford the first suspicion of its existence.

Headache. This is a more or less constant symptom, and though it may at first be intermittent and of slight degree, in the later stages it is often persistent and attains a severity which is rarely met with in headaches due to any other cause. It may be felt all over or localised mainly to the front, sides, or top of the head. It is often described as bursting or splitting, is frequently at its worst in the early morning, and is often associated with nausea or actual vomiting.

In the early stages the patient may be seized with paroxysmal attacks at considerable intervals, and even later on, when it becomes constant, the headache may at times become greatly intensified without apparent cause. Change of posture, such as stooping, or forcible expiratory movements, as in coughing or sneezing, often precipitate an attack or intensify pre-existing pain. Pain which is limited to the suboccipital region and radiates down into the back of the neck is strongly suggestive of a tumour in the posterior fossa. Headache which is always referred to the same spot, especially if it be accompanied by tenderness to pressure over this area, is evidence in favour of the growth being situated on the surface of the brain, or growing from the dura mater in this locality.

Vomiting is a less constant and a less frequent symptom than headache, but is present in the majority of cases. In its most characteristic form it is associated with headache and is independent of the taking of food. It is most marked in

tumours of the posterior fossa in which it may be an early symptom, sometimes preceding headache. Although the vomiting of cerebral tumour is often sudden and unassociated with nausea, this is by no means always the case. Waves of nausea may precede or may take the place of vomiting.

Papillædema is the most characteristic of all symptoms of increased intracranial pressure from cerebral tumour. Its appearances and the mechanism of its production have already been described (see pp. 620, 634). Whether it appears early or late in the disease will depend upon the factors already discussed under Pathology, and it must be borne in mind that its absence at any stage does not exclude the diagnosis. The condition is nearly always bilateral, but one optic disc may be affected before the other. The side upon which the papilloedema commences or is more intense bears no relation to the situation of the tumour. A high degree of swelling is compatible with good visual acuity, though the patient may complain of transient attacks of mistiness of vision. Permanent impairment of vision only occurs with the onset of secondary optic atrophy.

Convulsive attacks are not so frequent as the symptoms already mentioned, and they are very irregular in their occurrence in the cases attended by them; thus there may be two or three in the whole course of the illness, or they may be very frequent. They may take the form of generalised epileptiform attacks, in which there is an initial stage of tonic rigidity followed by clonic spasms and a temporary condition of stupor, or they may be limited to a momentary loss of consciousness. "Focal seizures" with characteristics distinctive of their origin in definite areas of the brain will be alluded to under the heading of Local Symptoms. They may, however, occur in the late stages of increased intracranial pressure without relation to the site of the tumour, and so be misleading and of false localising value.

Vertigo is not an uncommon symptom, and is usually associated with attacks of headache and vomiting.

Slowness of the pulse when it occurs is usually a late symptom of increased intracranial pressure.

Among other general symptoms are *mental changes*: the patient may be dull, apathetic, forgetful, sleepy, careless or untidy; in later stages he becomes lethargic, and finally comatose. These, however, occurring as the result of increased pressure, are late changes. In the early stages they are more commonly due to widespread destruction of the association fibres, such as is produced by large tumours of the cerebral hemisphere, and as such will be considered under Localising Symptoms.

Localising or Focal Symptoms. It is important to realise from the first that these are of greatest value in determining the site of the tumour during the earlier stages in its growth. In the later stages the mechanical effects of increased intracranial pressure may result in damage to parts of the brain, or traction upon cranial nerves, far removed from the site of the original lesion.

Tumours involving the motor centres and pathways give rise to symptoms of irritation or paralysis of the parts affected.

Paralysis in the form of a slowly progressive hemiplegia, with increase of deep reflexes, loss of the abdominal reflexes, and an extensor plantar response on the affected side, is produced by deeply seated growths involving the pyramidal fibres. Tumours situated more superficially and at first producing a local anæmia of the cortical centres frequently give rise to attacks of *Jacksonian epilepsy* of motor type. These are localised convulsions, beginning always in one part and unaccompanied at first by loss of consciousness. In these cases, according to the severity of the temporary disturbance in the part, there may be a twitching, say of the hand alone or of the hand and arm, or of all the muscles of one side of the body; if the convulsions spread to the other side of the body, consciousness is usually lost.

In their spread from the point of commencement the movements always show

a definite sequence. If they begin in the face, they spread successively to the upper limb, beginning with the thumb and fingers, and then to the lower limb; if they begin in the leg, the arm and face are successively affected; if in the arm, the face and leg in turn. The convulsions are usually followed by some degree of temporary paralysis, especially in the part first affected, and for a short interval after the attack changes in the reflexes may be demonstrated on the affected side in the form of diminished or absent abdominals and an extensor plantar response. With progressive increase in the size of the tumour and destruction of the centres at first irritated, the fits become less frequent and less extensive, giving place to permanent paralysis. If the growth is in the left hemisphere in the case of a right-handed person, some degree of aphasia will accompany the attacks, and remain with the paralysis, especially if the arm and face centres are chiefly involved. The aphasia produced will be at first of the motor type, though later this may be obscured by mental changes.

Tumours of the post-central regions in similar fashion produce progressive hemianæsthesia if deeply situated. This is limited as a rule to loss of sense of position and astereognosis in the affected hand, but there may also be a diminution in the subjective intensity of sensations of touch, temperature and pain, which is apt to be of "glove" or "stocking" distribution. Tumours involving the cortex give rise to Jacksonian attacks of sensory character, resembling the motor seizures in the manner of their spread, but consisting of a sensation of numbness or tingling, which is often attended with extreme discomfort. An attack of this nature frequently passes into a motor seizure of the type already described.

Tumours of the occipital lobe give rise to defects in the visual fields of the opposite side, the exact area of the defect depending upon the situation of the lesion. Superficial tumours of this region may cause attacks of subjective sensations of visual disturbance, usually in the form of flashes of light or colours in the opposite visual field. An occipital growth may by downward pressure upon the tentorium give rise to compression of the cerebellum, thus leading to signs of false localising value.

Tumours involving the uncinate gyrus give rise to peculiar attacks first described by Hughlings Jackson and known as *uncinate seizures*. These are in the nature of unpleasant sensations of taste or smell, indefinitely described by the patient in various ways as being "like the smell of rotten eggs," a "bitter taste as if a gumboil had burst in my mouth," and so on. This is often preceded by a dreamy state accompanied by visual hallucinations. The attacks may be quite momentary, or may occur in the form of auræ ushering in epileptiform convulsions.

Tumours of the frontal lobes frequently give rise to no localising signs of diagnostic importance, and the symptoms are therefore confined to those of general pressure. These may, however, be accompanied or preceded by mental symptoms to a degree unusual in the case of tumours elsewhere. The changes noticed are inattention, inability to keep the mind fixed on any subject, loss of memory for recent events, and incoherence in conversation. Sometimes these patients are childish, casual and irresponsible, and show a tendency to make silly and pointless jests at unexpected moments. In the later stages apathy and stupor supervene. A high proportion of cases of brain tumour discovered *post-mortem* in mental asylums are situated in the frontal lobes. Convulsive attacks may occur either of a generalised nature or beginning with conjugate deviation of head and eyes towards the opposite side from irritation of the centre for this movement in the pre-central area, in which case they are of diagnostic significance. A tumour of the anterior end of the frontal lobe may by pressure upon the olfactory tract produce unilateral anosmia. A tumour on either side involving the posterior part of the superior frontal gyrus may produce the symptom known as forced grasping or tonic innervation, a condition in which the patient having grasped an object or closed his fingers is for the moment unable to relax his grip. Distinct from this, but often associated with it, is the grasp reflex, an involuntary closure of the fingers

in response to tactile stimulation. A tumour in the posterior part of the left frontal lobe in a right-handed person is likely to result in motor aphasia and agraphia.

Tumours of the temporal lobe, apart from those at the anterior end, involving the uncinate gyrus, and those at the posterior end on the left side, involving the speech centres, may produce no signs of localising value, the symptoms being limited to those of general pressure. Changes in the sphere of intellect and temperament may occur as described in the case of frontal tumours. A deep-seated tumour in the temporal lobe is likely to involve the optic radiation and cause a defect in the opposite visual field.

Tumours of the corpus callosum do not, as a rule, cause very definite symptoms, but may give rise early to mental changes, and are sometimes associated with motor apraxia (*see p. 615*).

Tumours of the mid-brain may give rise to localising signs in the form of weakness of upward movement of the eyeballs, defective reaction of the pupil to light, eccentricity of the pupils, paresis or paralysis of the third cranial nerves, and defective sensibility over the area supplied by the fifth nerve, due to involvement of its mesencephalic root. Additional symptoms may arise from involvement of the longitudinal tracts in this region.

Tumours of the interpeduncular space, of which the commonest are the pituitary adenoma and the hypophyseal duct tumour, cause symptoms from pressure upon the optic chiasma. If the tumour, as often, is centrally situated the temporal half of each visual field is first affected, the defect of vision beginning as a para-central scotoma. When the tumour compresses the chiasma from below it is the upper quadrants of the fields of vision that are first affected, and the lower quadrants if the compression is from above. A tumour situated to one side of the midline will cause blindness of the eye on that side with a temporal defect in the field of the other. Associated with the failure of vision there is primary optic atrophy. In addition to this a suprasellar tumour may cause papilloedema.

The intrasellar tumours (mostly adenomas) give rise to severe headache of a continuous boring character, referred most frequently to the temples, though sometimes to the vertex or occiput. The suprasellar tumours (mostly hypophyseal duct tumours) cause headaches of the type generally encountered from increased intracranial pressure.

Other structures which may be compressed are one or other third nerve, with resultant ptosis and diplopia: the crus cerebri on one side leading to unilateral weakness with an extensor plantar response: and the nuclei in the floor of the third ventricle with resultant hypersomnia, and polyuria. The pressure effects upon bone are, as a rule, evident with the X-rays. The intrasellar tumour causes expansion of the sella turcica both in an antero-posterior and a downward direction (Plate 56, A). The suprasellar tumour causes erosion and finally disappearance of the clinoid processes, the size and depth of the sella remaining normal. In the majority of hypophyseal duct tumours (80 per cent. according to Cushing) calcification can be detected (Plate 56, B). The normal sella is shown in Plate 57 A.

Occasionally an intrasellar tumour may invade the nasopharynx and cause a leakage of cerebro-spinal fluid through the nose.

The glandular symptoms produced by the suprasellar and intrasellar tumours are described in the section dealing with the pituitary gland (*see p. 495*).

In *tumours of the pons* the localising signs depend upon affection of the cranial nerves situated therein, together with symptoms of destruction of the longitudinal tracts. Symptoms of general pressure are conspicuous by their absence until the terminal stages.

Tumours of the cerebellum frequently give rise to headache, which is at first localised to the suboccipital region, with a tendency to radiate downwards into the neck. Symptoms of general pressure appear early and are prominent. In addition there are nystagmus, inco-ordination in the performance of all muscular

movements, and reeling or staggering gait. In a tumour affecting mainly one lobe of the cerebellum, the headache may be mostly referred to that side, and there may be localised tenderness to pressure.

The tendency of the eyes is to deviate towards a point somewhat to the opposite side, so that nystagmus is coarser and more easily elicited when the patient looks toward the side of the tumour. There is frequently some degree of weakness, tremor, and hypotonia on the affected side of the body, and inco-ordination may be demonstrated in the performance of the finger-nose-finger, diadochokinesis, and heel-knee tests (*see* p. 627).

Characteristic peculiarities of attitude and gait are often present. There is a tendency for the head to be tilted towards the side of the tumour, and for the whole of the body to deviate towards that side. In consequence the ipsilateral shoulder is held higher than the other, and the ipsilateral lower limb is slightly abducted and everted, the former of these being of the nature of a compensatory mechanism for the spontaneous deviation.

In walking there is a spontaneous tendency to deviate or, it may be, to fall towards the side of the lesion, which is corrected by voluntary efforts, so that the patient may appear to stumble towards the sound side. In any doubtful case, the patient may be asked to stand on either leg alternately, when the greater weakness and unsteadiness of the affected side will be apparent. The reflexes as a rule are not altered, but the knee jerk on the affected side may show a pendular character when elicited with the leg hanging free, this being due to loss of muscular tone.

Tumours of the cerebello-pontine angle. These are characterised by progressive symptoms due to pressure upon the cranial nerves, succeeded by signs of a unilateral lesion of the cerebellum when the tumour has grown large enough to compress and destroy that structure. As already mentioned, symptoms of general pressure are of late onset, and usually coincide with cerebellar involvement.

The commonest growth in this situation is the neurofibroma of the eighth nerve known as *acoustic tumour*. This proclaims its presence first by symptoms referable to the auditory nerve in the form of roaring or whistling noises (tinnitus) and progressive nerve deafness. Next, the sensory root of the fifth nerve is involved, causing first diminution or loss of the corneal reflex on that side, and subsequently numbness and anæsthesia of the trigeminal field. At this stage the vestibular reactions normally obtainable by caloric, rotatory, or galvanic stimulation of the vestibular apparatus are found to be absent on the affected side. The seventh nerve is involved, with resultant facial weakness of peripheral type; nystagmus is present, being most marked when the patient looks towards the side of the lesion; and finally there ensue the signs already described as characterising a unilateral lesion of the cerebellum, together with headache, papilloedema and the other signs of increased intracranial tension.

False Localising Signs. It has already been stated that in the later stages of the growth of a cerebral tumour the mechanical conditions arising from increased intracranial tension may result in symptoms which have a false localising value. These may be produced by traction upon the cranial nerves, by thinning of the cortex from the pressure of internal hydrocephalus, or by the obstruction of some important vessel. The cranial nerves which are most commonly affected in this way are the sixth pair. Therefore a sixth nerve palsy developing late in the course of the symptoms of intracranial tumour is of negligible value as an isolated sign. The other cranial nerves which may be affected in similar fashion are the third, fifth, seventh and eighth. Thinning of the cortex probably accounts for the occasional occurrence of motor Jacksonian attacks and signs of involvement of the upper motor neuron tracts in these late cases. Downward pressure upon the tentorium from a tumour of the occipital lobe may give rise to cerebellar symptoms.

It is also an undoubted fact that in some cases of cerebral tumour with a high

degree of intracranial pressure the tendon jerks may be lost in both upper and lower limbs. The reasons for this are somewhat obscure.

The skull should always be examined carefully in a case of suspected cerebral tumour. In children it is frequently enlarged, with separation of the sutures, especially the fronto-parietal over which percussion yields a "cracked-pot" note. A slow-growing superficial tumour may cause erosion or hyperostosis of the overlying bone, and this is especially apt to occur in the case of a meningioma. The arterial angioma frequently gives rise to a bruit, appreciated by, and sometimes complained of, by the patient and audible by the physician on cephalic auscultation. A similar bruit may sometimes be heard over a vascular glioma.

The cerebro-spinal fluid may show an increased pressure to the manometer at a stage before other evidence of increased intracranial pressure is apparent. A pressure above 200 mm. of water is suggestive. In the later stages the pressure is often as high as 500 mm. On examination the fluid is frequently normal, but in some cases contains an excess of protein. This, as a rule, is unaccompanied by any increase in cells. Such a fluid is always suggestive of a vascular tumour from which transudation is taking place into one of the ventricles, and is also encountered with some regularity in the case of acoustic tumours. An increase of cells in the fluid may occur in the case of a growth which is necrotic and is near to the surface of the brain or of one of the ventricles.

The X-rays may reveal areas of calcification in the substance of the tumour. These are frequently seen in hypophyseal duct tumours, and less often in the chronic type of glioma (astrocytoma, oligodendroglioma) and the meningiomas. The venous angioma is almost always visible by this means. Abnormalities in the bones of the skull to be looked for are generalised thinning of the vault, and erosion of the dorsum sellæ from hydrocephalus, best seen in children; ballooning of the sella turcica in intrasellar tumours; destruction of the clinoid processes and erosion of dorsum sellæ in suprasellar tumours; local erosion or hyperostosis, or increased vascularity of the bone in meningiomas. In the antero-posterior view displacement to one side of a normally calcified pineal body may give evidence of a tumour in the opposite hemisphere. X-ray investigation may be carried further by the injection of air into the ventricles either by means of lumbar puncture (encephalogram) or puncture of a lateral ventricle through a hole drilled in the skull (ventriculogram). The X-rays then show the outlines of the ventricular system. In the case of a sub-tentorial tumour both lateral ventricles will be symmetrically distended, and the third ventricle visible between them in the antero-posterior view. A tumour of one hemisphere will cause deformation or obliteration of the lateral ventricle on that side with distension of the other, and displacement of the septum across the mid line. A tumour of the third ventricle causes symmetrical distension of the lateral ventricles, the third ventricle itself being obliterated or deformed. Air injections may be of great value in the localisation of tumours causing increased intracranial pressure with no unequivocal localising signs, but they are not without danger and should not be resorted to except with the co-operation of a surgeon who is prepared to carry out an operation at once, should symptoms of increased compression arise.

Diagnosis. When once the signs of increased intracranial pressure are established this is comparatively easy. The presence of persistent or constantly recurring headache of paroxysmal nature together with papilloedema is in nearly all cases evidence of a tumour of the brain. A condition which may require careful differentiation is that due to a *syphilitic meningitis*; other evidence of syphilis and a positive Wassermann reaction in blood or spinal fluid may help to clear up the diagnosis, and in this connection it is to be remembered that occasionally the reaction may be positive in the fluid though negative in the blood. A further possibility to be taken into account is that a patient with syphilis may also have a cerebral tumour. In doubtful cases the effect of anti-syphilitic treatment will be decisive.

The other causes of increased intracranial pressure which may simulate tumour are *chronic cerebral abscess* and *chronic subdural hæmatoma*. In the former a history of sepsis and in the latter one of head injury should be forthcoming, and the presence of polymorphonuclear leucocytes in the spinal fluid is always suggestive of abscess. Nevertheless abscess or hæmatoma are sometimes discovered only in the course of an exploratory operation for presumed tumour.

The clinical picture of a *hypertensive crisis* occurring in the course of arterial disease, with or without renal involvement may, sometimes resemble that of a tumour, but the fundus in the case of arterial disease as a rule shows retinal hæmorrhages at a distance from the nerve head, and characteristic changes in the retinal vessels. Finally the use of the sphygmomanometer will usually settle the diagnosis.

Hydrocephalus of the kind which may follow meningococcal meningitis, otitis media, and sometimes head injury is to be distinguished by the appropriate past history in each instance.

Encephalitis lethargica or other forms of encephalitis may occasionally give rise to difficulty. The absence of increased intracranial pressure as observed clinically and by lumbar puncture is the most useful point in excluding the diagnosis of tumour in such cases.

When the characteristic picture of increased intracranial pressure is absent the diagnosis of cerebral tumour is often extremely difficult and has to be distinguished from a variety of conditions.

The cases with progressive hemiplegia, hemi-anæsthesia or visual field defect have, in elderly persons, to be distinguished from the effects of vascular disease. Here the rate of progress is the most important point for it is almost always slower in the case of tumour than can be accounted for in terms of a cerebral thrombosis. In this group of cases the possibility of chronic subdural hæmatoma also has to be taken into account.

Epileptic attacks, focal or generalised, may occur in the early stages of idiopathic epilepsy, or as the result of syphilis, or an old vascular lesion or injury of the cortex. The differential diagnosis between cerebral tumour and idiopathic epilepsy may be extremely difficult, and is sometimes to be made only with the passage of time. It is a sound rule to suspect tumour in all patients beginning to have epileptic attacks in middle life without family history of the malady or other cause, and to investigate them from this standpoint.

The mental symptoms of cerebral tumour have to be distinguished from those of the other organic dementias, in particular those caused by syphilis and arteriosclerosis, and pre-senile dementia. The optic atrophy caused by pituitary and suprasellar tumours has to be distinguished from that due to other causes—in particular, syphilis.

Tumours of the cerebellum and brain-stem may sometimes cause symptoms liable to confusion with those of disseminated sclerosis, but the scattered symptomatology in the latter disease, together with the absence of increased intracranial pressure, usually suffices for the diagnosis.

Having determined the presence of a cerebral tumour and its situation it is often possible by taking into account, in addition to the symptoms, the age of the patient, and the results of special investigations such as X-rays and lumbar puncture, to be reasonably certain of its nature. This is especially true of the pituitary adenomas, and hypophyseal duct tumours, and the acoustic tumours. A mid-cerebellar tumour in a child is nearly always either a medulloblastoma or an astrocytoma, the former tending to occur at a rather earlier age, and giving a shorter history. A rapidly growing tumour deeply situated in one cerebral hemisphere in a person of middle age or older is almost certainly a spongioblastoma. A high protein content in the cerebro-spinal fluid will strengthen this suspicion. The X-ray appearances of the bone overlying a meningioma may be characteristic of this tumour. The intricacies of pathological diagnosis will

not be laboured further. The proper correlation of the information given in the sections on Morbid Anatomy, Pathology and Symptoms should enable the student to form his own suggestions.

Prognosis. In cases which are not subjected to operation the average survival period in a series of cases verified *post-mortem* was from one to two years (Tooth). It is naturally shortest in the case of rapid growths such as the spongioblastoma, medulloblastoma, and metastatic carcinoma. The life history of the more benign tumours may be much longer. The expectation of life is perhaps longest in pituitary tumours of simple type, which by reason of their situation within the sella turcica are precluded from causing increase of intracranial pressure until a very late stage in their development.

When once the signs of increased intracranial pressure have developed, blindness is likely to supervene from secondary optic atrophy. In the later stages also mental symptoms are likely to supervene. Death, which occurs from failure of the respiratory centres, may be extremely sudden.

The prognosis for various types of tumour with surgical treatment has been indicated in the section dealing with morbid anatomy.

Treatment. The treatment of syphilitic gumma is the same as the treatment of syphilitic meningitis (*see* p. 693). A tuberculoma may call for a decompressive operation for the preservation of vision. Otherwise the treatment is that adopted for tuberculosis elsewhere—rest, sunlight, and fresh air. The treatment of other cerebral tumours is almost entirely surgical, as described in the Morbid Anatomy section. Certain types of tumour of which the medulloblastoma, spongioblastoma, and metastatic tumours are the most conspicuous examples are better left alone, though an exploratory operation may be necessary in some cases to establish the pathological diagnosis. The medulloblastomas appear in some degree to be amenable to deep X-ray therapy, as also are the pituitary adenomas.

Medicinal treatment is limited to the relief of symptoms. Complete rest, ice-bags to the head, caffeine, phenacetin and aspirin in combination, and, lastly opium are the means available. Temporary relief from the symptoms of increased intracranial pressure may be obtained by means of hypertonic solutions such as 3 ounces of mag. sulph. in 6 ounces of water by the rectum, or 50 to 100 c.c. of a 50 per cent. solution of glucose intravenously.

CHRONIC HYDROCEPHALUS

By hydrocephalus is meant the accumulation of fluid within the cranial cavity. An acute effusion is mostly determined by meningitis, either tuberculous or meningococcal, and the former disease was once known as acute hydrocephalus.

A division has been made of chronic hydrocephalus into *internal* and *external* forms, according as the fluid is contained entirely in the ventricles of the brain or is formed outside between the brain and the skull, in the subarachnoid space. It is true that in old age, and from other conditions, the convolutions of the brain diminish in size, the sulci widen, and the space in the skull thus left by the disappearance of brain substance is filled up by fluid. Similarly a loss by local shrinking of the brain is replaced by fluid on the surface. But this compensatory secretion has none of the effects of true hydrocephalus. True external hydrocephalus is an extremely rare condition, the nature of which is not at present understood, but it is thought to arise as the result of chronic inflammatory changes in the meninges, and as such has also been termed serous meningitis.

Internal hydrocephalus, in which the distension is confined to the ventricles of the brain, may be divided into the congenital and the acquired types.

Congenital Internal Hydrocephalus. The condition is either noticed at birth or shortly afterwards, and must presumably depend upon some congenital abnormality in the secretion, circulation or reabsorption of the cerebro-spinal fluid.

There is no evidence in favour of the supposition that over-secretion on the part of the choroid plexus is the cause. Cases have been found in which a congenital block has been discovered in the Sylvian aqueduct or elsewhere, in the path between the fount of origin of the cerebro-spinal fluid, which is chiefly in the lateral ventricles, and the venous channels at the base of the brain into which it is reabsorbed (*see* p. 606). There remain, however, a large majority in which no such cause can be found, and the suggestion has therefore been made that the failure is on the part of the channels through which the fluid should normally be reabsorbed, and that the arachnoid villi in these cases are absent or defective.

This hypothesis remains unproven, but some support is lent to the idea by experiments showing that in animals, a small quantity of a suspension of finely divided particles of carbon (lampblack) being introduced into the subarachnoid space, these particles find their way to the arachnoid villi in the walls of the venous sinuses, and by thus blocking the channels for reabsorption of the cerebro-spinal fluid give rise to a picture of internal hydrocephalus in every way resembling that seen in man.

Morbid Anatomy. In this form of hydrocephalus, the ventricles of the brain contain an excess of fluid, sometimes amounting to a quart or more. It has the characters of cerebro-spinal fluid—that is, it has a specific gravity of 1,006–1,009, contains a small quantity of chloride of sodium, only a trace of albumin, and sometimes urea or cholesterin. The liquid may occupy all the ventricles, or all except the fourth, or the two lateral ventricles alone. By its increasing quantity the substance of the brain is enormously distended, the convolutions are flattened, sometimes reduced to a few lines in thickness, and the basal ganglia are correspondingly thinned out. The aqueductus Sylvii may be distended to the size of the finger when the fluid is in the fourth ventricle; it is often closed when the fourth ventricle is not dilated. In extreme cases the distinction between grey and white matter is lost in the parts exposed to most pressure; the ependyma is often thickened, and contains amyloid bodies, while its surface is covered with fine granulations.

Hydrocephalus is sometimes associated with other lesions of the central nervous system, *e.g.* spina bifida or syringomyelia.

Symptoms. The most obvious, and it may be for a time the only, symptom of the disease is the condition of the child's head which results from it. The pressure on the brain is transmitted to the skull, and as this expands outward the head becomes enlarged. The enlargement is often extreme. In congenital cases it may form a serious obstruction to delivery; in others it appears in the first few months of life, and the circumference may amount to 24 or even 32 inches, instead of 16 or 18 inches, which are the usual measurements up to the age of one year. The head is at the same time globular, and the skull projects over the face and neck almost uniformly all round. The face looks small and shrunken in proportion, and has a distressed, anxious, or senile expression in severe cases. The distension from within drives the orbital plates outwards, and the eyeballs are turned down so that the lower part of the iris and of the cornea is lost under the lower eyelid, and the upper part of the sclerotic is exposed. The increased size of the head is due to a separation of the cranial bones from one another, so that the fontanelles are much enlarged and the sutures widened. In these spaces fluctuation can sometimes be felt. In cases of long standing it is found that ossification has gone on at the margins of the bones, advancing into the sutures, so that ultimately, if the patient lives, by this means and by the formation, from independent centres in the membrane, of fresh plates of bone (*ossa triquetra*, Wormian bones), the deficiencies of the skull may be completely filled in. In the early stages, however, the bones are thin, wanting in diploë, and transparent. The skin of the scalp is tightly stretched, and excessively thin, and large blue veins ramify over the surface. The hair is generally scanty. In some cases,

where the fluid is not very abundant, the bones may yield sufficiently to obviate any considerable pressure upon the brain substance. The symptoms may not then go much beyond the enlargement of the head ; at most there is some general weakness and loss of flesh, from which after a time the child recovers. But in most cases there are other symptoms. The muscular power is deficient ; especially the large head cannot be held upright, and falls from side to side, or has to be supported by the hands when the child sits up in bed. The child cannot walk, or acquires the art in moderate cases only after a long time. Vision is often defective or lost ; and in extreme instances there is atrophy of the optic nerves. The other senses may be to a certain extent impaired. The intellectual functions are often defective. The child slowly learns to talk, continues childish out of proportion to its growth, and is fretful, irritable, or vicious in temper. Nystagmus, rigidity and spasms of the weakened limbs, convulsions, and vomiting occur often in severe cases. Many of these patients die young, relapsing into a condition of apathy or semi-coma, lying in bed with eyes closed or twitching, with rigid limbs and incontinence of urine and fæces, constantly moaning or whining, and refusing food or else eating voraciously.

Finally, convulsions, or coma, or some intercurrent disease, such as bronchitis, pneumonia, or measles, may end the scene.

In some cases the fluid has escaped by rupture of the integuments or by bursting through the nose or eyes.

Prognosis. The duration is variable. Few cases survive beyond the third year. In the mildest cases recovery may take place, or rather the disease is arrested. Sir Frederick Taylor recorded a case ("Clin. Trans.," 1897) where a lad reached the age of sixteen with perfect mental development and physical capacity, and died then with rapid cerebro-spinal symptoms, the ventricles containing 30 ounces of fluid. A few cases have lived to sixty or seventy years of age.

Diagnosis. Confusion is most likely to take place between this and rickets. The rickety head is cubical in form rather than spherical, the vertex being flattened ; the downward displacement of the eyeballs is absent ; the limbs may be feeble, but the mental powers are not deficient ; and the other evidences of rickets—beaded ribs, thickened wrists, sweating of the head, and general tenderness—are present at one time or another.

Treatment. In cases in which the Sylvian aqueduct and foramen of Magendie are not obstructed the distended ventricles may be drained by lumbar puncture. In the other cases in which there is an obstruction between the ventricles and the spinal subarachnoid space, drainage may be effected by ventricular puncture. But the effect is only temporary. Many attempts have been made to effect permanent drainage, but none so far have proved successful. Great care should be taken to prevent the development of bedsores from pressure of the tightly distended scalp upon the pillow.

Acquired Internal Hydrocephalus. This may occur either in children or in adults, but more commonly in the former. It is most commonly caused as a sequel of basal meningitis, particularly the meningococcal variety, by inflammatory adhesions which block the pathway of the cerebro-spinal fluid at its points of exit from the fourth ventricle. A similar blockage also occurs as the result of the mechanical conditions produced by tumours of the brain (see p. 724). It is especially likely to be caused by tumours directly blocking the Sylvian aqueduct even in their early stages. In addition there is a small group of cases to which the term otitic hydrocephalus has been given by the writer in which the symptoms develop during the course of or after otitis media, specially if this has been complicated by lateral sinus thrombosis. In some cases no satisfactory cause can be found.

Morbid Anatomy. The appearances in cases due to cerebral tumour have already been described. In the post-meningitic cases the foramina of Magendie and Luschka are obliterated by inflammatory material.

Symptoms. In the post-meningitic cases the condition of hydrocephalus closely follows the infective disease. In infants the enlargement of the head, together with the other symptoms described in the congenital form of the disease, are obvious signs of the condition. In older children and in adults the chief sign may be violent and persistent headache. The symptoms of increased pressure accompanying the condition when caused by cerebral tumour have already been described (*see* p. 725).

The rare cases for which no cause can be found when occurring in adults present symptoms of increased intracranial pressure, which can hardly be diagnosed from those of cerebral tumour. The distension of the third ventricle may give rise to optic atrophy from pressure upon the chiasma, and to paralysis of upward movement of the eyes from pressure upon the superior corpora quadrigemina.

The **Prognosis** depends upon the cause. In cases due to cerebral tumour it has already been discussed. Of the post-meningitic cases some children may eventually recover, but are often epileptics or mentally deficient; in adults the condition may continue for some months and then terminate suddenly in a fatal issue with failure of respiration. In the cases of obscure origin (primary acquired hydrocephalus), the outlook is more hopeful: there may be remissions or intermissions lasting in some cases for years.

Treatment. In the post-meningitic cases ventricular puncture and drainage have been recommended with subsequent introduction of anti-meningococcal serum. In those due to cerebral tumour the treatment has already been considered. The otitic cases can be relieved by repeated lumbar puncture with drainage of the cerebro-spinal fluid. Eventually the pressure falls to a normal level and permanent relief is obtained.

GENERAL PARALYSIS OF THE INSANE

Syphilitic Meningo-encephalitis

Pathologically this disease is characterised by widespread degenerative and inflammatory changes in the brain, caused by the spirochæte of syphilis, clinically by progressive mental deterioration together with certain physical signs, and in the last stages generalised paralysis. The title by which it is usually known dates from the time when the disease was thought to be a complication occurring in some cases of insanity, and should long ago have been abandoned in favour of a more scientific terminology. But the old name has an established usage.

The disease is much more frequent in men than in women, and occurs mostly between the ages of thirty and fifty, five to fifteen years after infection.

Cases also occur in children or young persons as the result of congenital infection.

Morbid Anatomy. The meninges as a rule are thickened with adhesions between themselves and to the surface of the brain, so that when an attempt is made to strip the pia-arachnoid the cortex is torn. The brain itself is usually smaller and lighter than is normal; the gyri, especially in the frontal lobes, appear shrunk, and the sulci by comparison wide and full of fluid. The ependymal lining of the ventricles is thickened, opaque and irregular, giving rise to a "frosted" appearance.

Microscopically there is a proliferation of the endothelial cells of the vessels with peri-vascular and diffuse infiltration of the cerebral substance with cells. Amongst these are found lymphocytes, plasma cells and various forms of neuroglial cells. Nerve cells and fibres are to be found in various stages of degeneration. There is also a marked increase in the neuroglial fibres. Areas of actual disintegration and softening may be found, but are not a characteristic feature. The spirochæte pallida, originally discovered in the brain by Noguchi and Moore,

in 1913, has subsequently been demonstrated in many other cases. It is, however, sparse in its distribution and found only if assiduously looked for. Degenerative changes consequent upon the cerebral lesions may be found in the spinal cord, and in a number of cases there is a simultaneous degeneration of the posterior columns (tabo-paresis).

Symptoms. Considerable difference is seen in the grouping of the symptoms; the nature of the mental changes in the early stages is variable, and there is no parallelism between physical and mental symptoms, nor between individual physical signs.

Most frequently the earliest symptoms appear in insidious changes in the personality. The man becomes careless or neglectful, tends to intemperance in drink, or spends more money than has been his wont without justification, or he is irritable or restless, changing in his affection towards his wife or family, or jealous without a cause. On the other hand, the early picture may be simply that of neurasthenia, with complaint of abnormal fatigue, sleeplessness and irritability. Headaches may be a prominent symptom, depending, no doubt, upon the meningeal involvement. The intellectual faculties are as a rule involved moderately early. There are defects in memory for the remote as well as the recent past, with consequent discrepancies in the dating of events in the patient's history. As a rule he possesses no insight into these defects, and will maintain that his memory is as good as ever. Disturbances of mood are frequent, the commoner type being that in which the patient is extremely elated, active and voluble, with delusions of grandeur. These concern himself alone; they express what he is, what he possesses, or what he can do. He is the Almighty, the King of England, or the Prime Minister, the most handsome or the most powerful man in the world. He has invented the most ingenious devices for making money, and is already possessed of boundless wealth. On the other hand, the dominant mood may be one of extreme depression, characterised by an extravagance of delusion which helps to differentiate it from a simple melancholia. In this condition the patient may attempt suicide. Yet another type of onset is that which shows itself in progressive apathy and deterioration of interests without any underlying disorder of mood.

Not infrequently the earliest symptom to attract attention is the occurrence of epileptic attacks. These may be of a minor or major variety, generalised or focal. They occur sooner or later in most cases of the disease.

On the physical side the facial muscles are smoothed out and expressionless, and there is commonly a tremor of the lips and cheeks in speaking. Speech is slovenly and slurred, with a tendency to miss syllables in the pronunciation of difficult phrases (such as "Methodist Episcopal"). Primary optic atrophy is sometimes present. There is a fine tremor of the protruded tongue, and there may also be atrophy from involvement of the hypoglossal nuclei. Pupils of the Argyll-Robertson type may be seen early in the illness, and are seldom absent in the terminal stages. Tremor of the outstretched hands is commonly seen, and shown also in the handwriting. The condition of the tendon reflexes in the early stages varies with the degree of involvement of pyramidal and posterior column fibres. Extensor plantar responses may be found either with exaggerated or absent knee and ankle jerks.

Occasionally apoplectiform attacks may occur with hemiplegia. This is often associated with high fever, and is characterised as a rule by a much more rapid improvement in the physical signs than is seen in cerebral hæmorrhage or thrombosis.

In the later stages there is wholesale deterioration, both mental and physical, with loss of sphincter control, and the patient dies as a rule from cystitis, pneumonia or other intercurrent infection.

Syphilitic encephalitis (Juvenile G.P. 1) is found, though rarely, in children the subjects of congenital syphilis, either manifesting itself from the first in

mental deficiency or giving rise to progressive deterioration at or after puberty. In these cases optic atrophy is common.

The Wassermann reaction in the blood is positive in 95 per cent. and in the spinal fluid in 100 per cent. of all cases. The pressure in the spinal fluid is usually raised—in the neighbourhood of 200 m.m. H₂O, there is an increase of cells which are mostly mononuclear but with an occasional polymorph or plasma cell, and the protein is increased up to 0.1 per cent. The colloidal reaction is constantly of the paretic type, precipitation being complete in the first three or four tubes of the series.

Diagnosis. The mental condition in *cerebral arteriosclerosis* may simulate that of *dementia paralytica*, but in the former disease the memory defect is more usually confined to recent events, and is recognised by the patient. *Alcoholism* may be mistaken for general paralysis, the tremor of the lips, tongue, and hands largely contributing to this; commencing *peripheral neuritis* might further complicate the case. But the close association of the symptoms with continued drinking, the absence of inequality of the pupils, and the improvement on prolonged abstinence, would point to alcoholism. Mental failure with definite cerebral lesions such as *tumours*, or the dementia resulting from bilateral vascular lesions (*pseudo-bulbar palsy*), may give rise to difficulties. Certain cases also of *disseminated sclerosis* with early cerebral involvement may require careful differentiation.

The positive signs of greatest value are the pupillary changes and slurring speech. A history of syphilitic infection is, of course, of the greatest importance.

The diagnosis can as a rule be made with certainty by examination of the blood and spinal fluid.

Prognosis. The course of the untreated disease is as a rule progressive to a fatal termination within five years of the time when clinical diagnosis is possible. There may, however, be remissions, and in a few cases spontaneous arrest has been reported. It is therefore difficult to gauge the effects of treatment.

Treatment. Malarial infection is now generally accepted as the best treatment for this disease. This is generally carried out by withdrawal of 5 c.c. of blood from the vein of a person with active malaria into a syringe containing a few drops of 5 per cent. sodium citrate. This is injected subcutaneously into the patient. The benign tertian parasite is that generally used and the incubation period varies from a few days to four weeks. The patient is allowed to have twelve rigors, and the infection is then cut short by the administration of quinine sulphate gr. 15 a day for three days, and gr. 10 daily on the succeeding eleven days. This is followed, as a rule, by a course of injections of novarsenobillon. The results claimed from this treatment are a high percentage of remissions—30 per cent. of the cases treated—which may last for a number of years and enable the patient in some instances to return to his work, and in other cases arrest of the disease and prolongation of life. Against this must be set a mortality rate of 15 per cent. from the treatment.

From the broader standpoint of the patient's friends and relations and the general community early diagnosis is most important, that all may be warned, and the patient if necessary be committed to a proper institution before he bring ruin upon his own fortunes and reputation, and endanger the welfare of others.

Huntington's Chorea. This is a rare disease *sui generis* to be sharply distinguished from the form of chorea already described, though in some ways it resembles it. It is a hereditary affection of middle life, of progressive nature, leading to dementia.

Ætiology. Heredity plays the most important part in the disease. It is transmitted from one generation to another, though occasionally the members of one generation may be spared. Men and women are equally affected, and the disease usually begins between the ages of thirty and forty. As the result of a genealogical research conducted in the United States of America 900 cases of

the disease were traced back to three brothers who landed in America from England early in the seventeenth century.

Pathology. In certain cases carefully examined chronic diffuse or disseminated inflammatory changes have been found in the brain and meninges.

Symptoms. The cardinal symptom is motor restlessness of a type similar to that seen in the chorea of children. There is a constant and rapid succession of purposeless inco-ordinated movements of all kinds, affecting all parts of the body. These movements show a tendency to affect the proximal groups of the limb musculature to a greater extent than occurs in the chorea of children. The limbs are consequently thrown about with considerable force, and the gait is grossly affected. The movements may be temporarily inhibited by voluntary effort.

Mental changes are constantly associated with the disease, at first in the form of irritability and restlessness, sometimes leading to suicidal depression, and finally terminating in progressive dementia of organic type, so that these patients, as a rule, end their lives in mental institutions.

The **Prognosis** is hopeless, the duration of life being from ten to thirty years.

The **Treatment** is symptomatic only.

There remain to be described certain diseases in which the signs and symptoms point to disturbances of function in the nervous system, for which, however, no structural basis can be found *post-mortem* either with the naked eye or by our present methods of microscopical examination.

EPILEPSY

(*Idiopathic Epilepsy, Genuine Epilepsy*)

Epilepsy has already been spoken of as a *symptom* of certain diseases of the brain, particularly those which affect the cortex (e.g. cerebral tumour, encephalitis, syphilis of the brain), and also of some toxic states of which uræmia is the chief example. The attacks provoked by such causes differ in no way from those presently to be described. Epilepsy in all cases probably depends upon disordered function of the brain, whether this is due to congenital defect, to local disease or injury, or to the effect of circulating toxins with a selective incidence. But in the very large majority of cases we are unable by present methods to discover any such cause. The attacks continue indefinitely without the appearance of any further signs of disease, and if an autopsy be obtained microscopic examination reveals no abnormality of the brain. It is this group of cases which, in our present ignorance of their pathology, we are obliged to group together under the symptomatic title of epilepsy.

Epilepsy, therefore, may be defined as a disease in which there are attacks of sudden loss or impairment of consciousness, with or without convulsions, or occasionally of convulsions without disturbance of consciousness, independent as far as our present knowledge goes of any demonstrable lesion of the brain, or state of toxæmia.

Ætiology. The disease is rather more common in females than in males. In about one-third of all cases there is a history of epilepsy in the family. Three-quarters of the cases begin under the age of twenty. The age of onset in the remainder is evenly spread over the remaining decades. Thus idiopathic epilepsy being on the whole a common disorder it is by no means rare to meet with cases beginning in adult life or even in old age.

In a small percentage of cases the seizures appear to be directly related to previous injury to the head with cerebral contusion (*see* p. 712). The interval between the injury and the first attack may cover several years. The clearest proofs of such relationship are cases in which the attacks commence with symptoms directly referable to the site of the injury, as in the case of a gunshot wound over the left motor cortex, and subsequent fits beginning with convulsive movements in the right side of the body. Even in these cases, however, the hereditary influence is sometimes apparent. Occasional causes for the attacks are sometimes

to be found. Chief among these are mental fatigue, excitement, or anxiety. Lack of sleep, physical fatigue, and fasting may also precipitate attacks. In some cases there is a definite relation to menstruation—the attacks occurring as a rule at the onset of the period. Some cases may possibly be allergic in origin.

Pathology. By the definition given above all cases are excluded in which a pathological cause for the epileptic attacks can be found. We are limited, therefore, to speculation. Arguing from the known causes to the unknown, we have reason to believe that epilepsy depends either (1) upon defective function of the cerebral cortex, congenital or acquired, or (2) upon the presence in the body of poisons with a selective action upon the cortical nerve cells.

Symptoms. The essential feature in most cases of epilepsy is a disturbance of consciousness, which usually, but not always, amounts to complete loss. With this in the majority of attacks there are associated convulsive movements.

It is convenient to distinguish between “major” and “minor” forms, according to the severity of the convulsive movements, but there is no absolute line of distinction.

In *Major Epilepsy* or “*Grand Mal*” there are usually to be discerned several stages: (1) aura; (2) unconsciousness and tonic contraction; (3) clonic convulsion; (4) recovery. The *aura* (or breath, from the sensation of air passing up the limb to the head, which is one form of this symptom) is any sensation or motion experienced by the patient while he is yet conscious, mostly of very short duration, and terminating abruptly in loss of consciousness and convulsion.

1. The aura is absent in about one-half of the cases. In the others it may assume a variety of forms, of which the following may be mentioned as of common occurrence: tingling and numbness in the arm, leg, face, or tongue; twitchings or spasms in the same parts; loss of vision, or visual hallucinations, such as flashes of light, or colours (generally red or blue) or definite objects or enlargement of surrounding objects (*megalopsia*); hallucinations of sound, noises, etc.; unpleasant odours or tastes; sensation of choking, nausea, vertigo, epigastric pain; flushes of heat, coldness, perspiration, palpitation of the heart; an indefinite sense of fear or anxiety; a *dreamy state*, or sense of unreality, or the feeling that what is happening has occurred before; running or jumping, or other co-ordinated movement. Auræ of sensation and motion are mostly unilateral, but may be bilateral; the arm is more often affected than the leg, and facial auræ mostly consist of spasm. Sometimes a vague sense of fear may last some time before the occurrence of the actual fit; but, as a rule, the aura is of momentary duration.

2. The fit itself commences with sudden unconsciousness; if standing or walking, the patient often falls suddenly forwards, or seems to be thrown violently to the ground, sometimes with an involuntary cry, shriek, or low tremulous groan—the epileptic cry. He is then found to be in a state of tonic convulsion, the back rigid and slightly arched, the legs extended, and the head drawn backwards or rotated to one side. The face is often pale at first; the pulse is quick, but sometimes it cannot be felt, and this has been attributed to compression of the artery by muscular contraction; the pulse has also been observed to cease at the moment of unconsciousness. The general tonic contraction fixes the chest, and respiration is stopped, so that the face becomes more and more dusky, and eventually is quite cyanosed. The tonic stage lasts from three to thirty or forty seconds, and then passes into the stage of clonic convulsions.

3. Twitchings begin in the face, the eyelids, and the side of the neck, and quickly extend to all the muscles of the body and limbs. There is a rapid succession of to-and-fro movements, of alternate flexion and extension in the limbs, of opening and shutting of the eyelids and of the jaws, lateral deviation of the eyeballs, and perhaps of the head; the tongue is pushed forward, and may be caught between the teeth; saliva is freely secreted, frothed in the mouth, and escapes from the lips mixed with blood from the bitten tongue. The face becomes

livid, or almost black, and the lips and features are swollen. Urine, fæces, and semen may escape during this stage, and the violent contraction of the muscles may even cause dislocation of the shoulder. The patient is, of course, quite insensible; the conjunctivæ do not respond to a touch, and the pupils are dilated or oscillate.

4. The clonic stage lasts a few minutes, rarely more than five or six, and then the convulsions gradually subside—they become less frequent, and are interrupted by pauses of some seconds; the breathing becomes easier, the frothing at the mouth ceases, and the face gradually assumes a more normal colour. Finally, the patient remains simply comatose, and the coma passes into natural sleep, or consciousness is recovered rather suddenly soon after the cessation of the convulsions. When consciousness is finally regained the patient is as a rule dazed and complains of headache.

The reflexes are mostly absent for a short time after the attack, and then for a time the deep reflexes may be increased. The plantar reflex after a temporary absence is at first extensor, then again normally flexor. The urine may contain a trace of albumin or sugar; petechiæ may be seen under the skin from rupture of blood vessels during the stage of venous congestion; sometimes there are vomiting, or serious mental disturbances, such as delirium, which is often of a maniacal kind.

The mechanical injuries from which the epileptic suffers will, of course, remain after the fit, and may give valuable indications in cases where the fit has not been seen—for instance, in nocturnal epilepsy. These are the bitten tongue, petechiæ on the skin, a dislocated shoulder, and, in other cases, various cuts, wounds, or bruises, from the falling of the patient upon the ground or against unyielding objects.

Minor Epilepsy or "*Petit Mal*." This consists, in a large number of instances, of little more than a sudden unconsciousness; in the midst of talking, perhaps, the eyes become fixed, the pupils dilated, the speech incoherent, and the patient is obviously unconscious of what is going on around him; he may, if at meals, put his fingers in his plate or his cup, or commit some other irregularity that he would not do if conscious. The condition lasts a few seconds, and then he becomes conscious, and goes on with what he was doing, or perhaps recognises that there has been a blank, or feels giddy, or has headache, and is glad to lie down for some time. Sometimes giddiness is the most marked feature of the attack, and in other cases a sensation in one or other part of the body, or a spasmodic movement, which may be quickly followed by temporary unconsciousness, though the former will seem to the patient the chief feature of the attack. These have a close resemblance to the auræ of the major attacks, and include sensations in the epigastrium, hands, head, nose, eyeballs and cardiac region; olfactory and visual sensations; jerks in the limbs, head, or trunk; sudden tremor, screaming, or dyspnoea; mental conditions, such as a sudden state of fear, etc.

In many instances there is no complete loss of consciousness. The patient is aware of his surroundings and often of what is being said by those around him, but everything for the moment appears distant, he fails to comprehend the full significance of events and is incapable of formulating his thoughts clearly.

Jacksonian or Focal Epilepsy. Whether in a major or minor attack the symptoms may be of a generalised or focal character. An epileptic attack of focal type is frequently called Jacksonian after Hughlings Jackson, whose clinical observations upon epilepsy provide the foundation of our knowledge of this aspect of the subject. Focal attacks are those in which the symptoms may be attributed to a disturbance arising in some particular area of the cortex. Thus they may be motor or sensory, and if the latter, of a general or special type. In the motor attacks there is tonic followed by clonic spasm in the muscles of one

limb or part of a limb; this tends to spread so as to involve the whole of one side of the body. The convulsive movements may then become generalised, and if so consciousness is lost. Or they may remain localised, in which case there is sometimes no loss of consciousness. In similar fashion a disturbance of bodily sensation, smell or taste, hearing or vision may usher in a generalised attack or may itself constitute the only evidence of the epileptic episode. It is important to recognise that the nature of such attacks indicates only the situation of their origin and provides no clue to their pathology. A focal or Jacksonian attack is not necessarily of organic origin. Indeed, the commonest cause of focal attacks is idiopathic epilepsy. It may be said, however, that attacks which remain localised, that is, without going on to a generalised convulsion, and particularly focal attacks in which there is no loss of consciousness, are generally due to organic disease of the brain.

Pyknolepsy. This condition, which is considered by some clinicians to deserve a separate title, is by others regarded as a form of *petit mal*. In so far as the attack itself is concerned there is certainly no distinction. The features which distinguish the malady from other forms of epilepsy are the onset (usually abrupt) in childhood, the occurrence from the first of repeated attacks—six to fifty a day—of uniform and mild degree, absence of any mental deterioration, failure to respond to the drugs usually effective in epilepsy, and cessation of the attacks after puberty. Thus the complete diagnosis is only permissible after the attacks have ceased, but the forecast of a happy issue may sometimes be made upon the basis of the other points enumerated.

Post-epileptic Conditions. The attack is generally followed by a period of drowsiness and often by severe headache. A serious psychical disturbance is a not uncommon sequel to an epileptic fit, and follows the minor attack even more frequently than the major. It may take the form of stupor lasting some days. In another case various *automatic* actions occur of which the patient is then and afterwards entirely unconscious. Perhaps the commonest of these is the act of undressing, which in a public place may lead to a charge of indecent exposure, or the patient may put in his pocket any object which happens to be near, irrespective of its ownership. Occasionally he may be violent and aggressive, and while still in the automatic state cause bodily injury to others. These cases have great medico-legal importance, since the occurrence of epileptic fits may be quite unknown, and the criminal behaviour may be attributed to wilful and conscious action. Sometimes these attacks are maniacal in their character (*epileptic mania*), and the automatic actions are accompanied with much mental disturbance, such as terror, violent passion, delusions, and hallucinations.

Equally important, on account of the difficulty in diagnosis which they occasion, are minor psychical sequelæ. The patient recovering from an attack of true epilepsy frequently behaves in a childish, emotional manner, weeping and laughing alternately, and will sometimes pass into a hysterical “fit.”

Course of the Disease. The frequency of epileptic attacks varies considerably in different cases, and at different periods in the same case. Thus there is generally an interval of one or more months between the first and second attacks, but with the progress of the disease the intervals often become shorter, and the fits may be as frequent as two or three in a week, or even several in a day. In some cases two or three fits occur in quick succession, or at short intervals, and the patient is then spared for a long time. A severe fit is much more likely than a slight one to be followed by a long interval. Probably alcoholic indulgence, injudicious feeding, and mental or physical over-exertion, increase the frequency of the fits.

Status Epilepticus. In rare instances the patient has a series of fits, extending over some hours, or one or two days, and never recovers consciousness in the intervals between them. The heart beats violently and rapidly, the respirations are quick, twitchings occur in the intervals of the convulsions, the

temperature often rises to 105° or 107°, and the patient may die collapsed, or may become delirious.

Health between the Attacks. This depends a good deal upon the frequency of the fits. Where these are not numerous, the individual may enjoy excellent health. Many epileptics are strong, hearty, and vigorous, never ailing at all except at the time of the attack. When, however, the fits are very frequent, or the disease has lasted a long time, the mind generally suffers, the patient becomes dull and irritable, the memory is deficient, and intellectual processes are slower, until eventually a condition of *dementia* is reached.

Death from epilepsy is by no means common, and, except in the case of the rare status epilepticus above described, it is mostly the result of some injury to which the patient is exposed during the fit. Thus during a fit he may be thrown from a height, or fall into water and be drowned, or be choked by food, or he may be smothered in bed by his face being buried in the pillow, or he may die later from injuries received by a fall into the fire, or from a carriage or bicycle.

Diagnosis. Epilepsy is with no great difficulty recognised when actually seen, but one is often called upon to prescribe for fits which only occur at times when the physician cannot witness them; and it is not always easy to come to a right conclusion from the descriptions of friends. The major attacks have to be distinguished from attacks of hysteria, and from simulated fits, minor epilepsy from attacks of syncope or vertigo. Hysterical attacks seldom, if ever, occur when the patient is alone or unlikely to attract an audience. The onset is seldom so dramatically sudden as in epilepsy, and the attack is usually related to an emotional stimulus. The movements in the hysterical fit never consist of simple tonic or clonic jerkings, but are of a more purposive character. Thus the patient will clutch at those around her, dash her head against the wall or floor, clench and unclench the hands, or bite at those who seek to restrain her. The convulsive movements of epilepsy are over in a few minutes. The motor phenomena of hysteria last as a rule much longer. The hysterical patient frequently talks during the attack; the epileptic never. The hysterical patient never falls so as to hurt herself severely, nor does she bite her tongue or pass water in the attack. In the hysterical fit the eyelids are often tightly closed, and attempts at opening them are resisted. The occurrence after the fit of mental disturbances and the exaggeration of deep reflexes with loss of abdominal reflex are in favour of epilepsy, while an extensor plantar response obtained after the attack is conclusive evidence of its epileptic nature.

It must not be forgotten that an attack of epilepsy may be immediately followed by one of hysteria, and that the same patient may at different times exhibit epileptic and hysterical fits.

The *malingerer*, who attempts to excite sympathy as a sufferer from epilepsy, can, with a little care, generally be detected. He is careful to fall so as not to hurt himself, whereas the epileptic is thrown down suddenly, and if in the street will probably strike his head or face, or will fall in the road, not making any effort to save himself. The malingerer is red in the face rather than pale or livid; his skin perspires from the exertion; his pupils are not dilated and are sensible to light. The fact that he has not lost consciousness may be tested in various ways: by touching the conjunctiva, when the eyelids will close, though he will probably resist attempts to raise the upper eyelid; by applying snuff to the nostrils; by producing some very painful impression, as by forcing one's thumb-nail under that of the malingerer.

Minor epilepsy, or *petit mal*, is distinguished from *cardiac syncope*, or simple fainting, by its occurrence under circumstances not conducive to fainting, by its suddenness, and by its rapid recovery, followed by mental confusion rather than physical prostration. The occurrence of spasm or of any warning sensation other than the feeling of faintness is in favour of epilepsy. Syncope comes on more slowly, and is recognised as a gradually increasing faintness by the patient. Still

this may happen as a warning sensation of *petit mal*. To distinguish other forms of *giddiness* from the vertiginous form of minor epilepsy, one must remember that ordinary vertigo is not accompanied by loss of consciousness, and that in the aural form, or Menière's syndrome, a history of tinnitus and deafness may be obtained.

When it has become certain that, in any case, the attacks are really epileptic, it has yet to be determined that they are not due to tumour of the brain or cerebral syphilis, the uræmia of Bright's disease, or other organic disease, before one can pronounce the disease to be epilepsy. In a great number of cases of idiopathic epilepsy, the long history of recurring convulsions with no associated symptoms will serve to distinguish it, whereas in *cerebral tumour* there will probably be other indications, such as headache, vomiting, papilloedema, or local paralysis. Nevertheless epileptic attacks may for many months be the only symptom of a cerebral growth. Attacks of epilepsy frequently usher in *general paralysis of the insane*, and in the absence of all other signs may be the first warning of the disease. For this reason epilepsy commencing in a man of middle age must always be suspect. The pupils and mental state must be carefully examined and the Wassermann reaction obtained if necessary in the spinal fluid as well as in the blood. In *Bright's disease* the convulsions are epileptic, but the patients, as a rule, show good evidence of their state of health in albuminuria, high tension of pulse, hypertrophy of heart, raised blood urea preceding uræmia; the fits are often ushered in by drowsiness and muscular twitchings, are of much longer duration, and recur frequently in the same day with intervals of drowsiness or semi-coma.

Epileptic attacks may also occur as a sequel of *cerebral contusion* often after a latent interval of two or more years. The attacks may be focal or generalised. As a rule the history will be that of a major contusion (see p. 712).

These are perhaps the commonest causes in the way of organic disease which may cause epileptic attacks, but they may occur in the course of any malady involving structural damage to the brain, such as encephalitis, cerebral arteriosclerosis, Schilder's disease, cerebral diplegia, the infantile and juvenile forms of Tay-Sach's disease, or in certain toxæmias other than Bright's disease such as chronic alcoholism, insulin hypoglycæmia, and alkalosis.

Prognosis. Nothing is more difficult than to forecast the future of an individual who has had an epileptic attack for which there is no apparent cause. In the large majority of cases, and especially if the trouble begins in childhood, the attacks continue at irregular intervals throughout life. The intervals, however, in many cases are so long that the patient is not seriously handicapped in the pursuit of a normal existence. In some cases the attacks may cease, never to return, but the percentage in which this may occur as commonly given in statistics is almost certainly overrated. It is not uncommon to find an epileptic after fifteen or twenty years' complete freedom having further attacks. The *liability*, once present, probably always persists, and this must be taken into account in making plans for the lives of these patients. There is a tendency for attacks which are either diurnal or nocturnal to remain so. Mental deterioration occurs in a considerable proportion of cases, especially when the attacks are frequent and severe. There is, however, no constant rule in this. One may occasionally see a patient with relatively few fits and progressive dementia, and, on the other hand, one with many more attacks whose mental faculties are preserved. It must not be forgotten that epileptic attacks may be the first, and for a time the only, evidence of cerebral tumour. It is wise, therefore, in the early stages of the malady, especially in adults, to give a guarded prognosis.

Treatment. *General.* It should be recognised that the liability to attacks is in most cases likely to be lifelong, and is in itself a severe handicap and source of annoyance. The epileptic should therefore be subjected to as few restrictions as may be essential to his well-being and safety. Fortunately, the loss of consciousness, which is usually a feature of the major attack, renders the patient unaware

of the symptoms which are most distressing to his friends. The story of these, as obtained from a witness, should never be taken in the patient's presence. A regular life with adequate sleep, recreation and occupation is to be advised. Late nights and the excessive use of alcohol and tobacco should be forbidden. Dietetic restrictions are probably unnecessary, with the exception of the ketogenic diet to be mentioned later as an occasional resource. No epileptic should drive a motor car under any circumstances, or ride a bicycle on crowded roads. Nor should he bathe unless accompanied by someone who is aware of his liability. Apart from these restrictions he is best allowed to live an ordinary existence, and may be encouraged with the assurance that many persons who carry this liability lead happy and successful lives. That such a policy carries its risks of accident there is no doubt, but it may fairly be pointed out to the anxious parent that the alternative of complete safeguarding would render life unendurable. Advice is often sought on the question of marriage. This has no effect upon the individual. Women are, on the whole, likely to have fewer attacks during pregnancy. There is, however, a risk that the liability may be transmitted to the offspring. This, so far as the first generation is concerned, is slight, probably not more than one in twenty. But it is to be remembered that in about 30 per cent. of all epileptics a history of the complaint is obtainable somewhere in the family tree. In the case of a male the attacks may limit his earning capacity.

Medicinal. Many drugs have been used for the treatment of epilepsy, among which bromide still holds first place. The potassium salt is most generally used. It should be given at first in small doses, 10 grains night and morning for an adult, and is usually prescribed with 1 or 2 minims of liquor arsenicalis, which is said to diminish the liability to skin eruptions. If necessary, the dose may be increased up to 15 or 20 grains thrice daily. Many patients tolerate such doses without ill-effect. Others will complain of dulness or depression. The individual idiosyncrasy to the drug must be studied and the dose graduated accordingly.

Luminal is sometimes effective where bromide fails, or may be given together with bromide. The dose is up to 5 grains in the twenty-four hours, but on this maximum most patients are drowsy and some will show other toxic symptoms, such as giddiness or an erythematous rash. If given alone, $\frac{1}{2}$ grain thrice daily in tablet form is a suitable dose, to be increased if necessary. Luminal sodium being water soluble may conveniently be prescribed together with bromide, a suitable prescription for an adult being :

Potassium bromide . . .	10 grains.
Luminal sodium . . .	$\frac{1}{2}$ grain.
Liquor arsenicalis . . .	Mj
Chloroform water to the ounce.	

Twice or thrice daily.

Prominal as a substitute for luminal is said to be less apt to cause unpleasant drowsiness. $1\frac{1}{2}$ to 3 grains may be given twice or thrice daily.

Of other drugs, the tincture of belladonna, 10 to 15 minims, may be given thrice daily, and is sometimes effective when bromide and luminal fail. Sodium biborate in doses of 10 to 15 grains thrice daily is also sometimes of value, and having no depressing effect may be used to replace or reinforce bromide. Gelineau's Dragées, which contain picrotoxin together with bromide, occasionally seem to succeed when other remedies have failed. To be given a fair trial, any one of these drugs should be administered continuously over a period of weeks or months.

During the Attack. In cases where there is a definite aura the attack can sometimes be arrested. If the aura consists of a sensation in the hand, which gradually proceeds up the arm, the fit may possibly be checked by vigorously rubbing the part, or by tightly constricting the arm above the seat of the sensation, thus preventing, as it were, its progress to the centres. Where this is successful the patient may wear a cord looped round the upper arm, with one end conducted down his sleeve to the wrist, so that by pulling upon this end he can at once

constrict the arm. Other patients may be able to ward off fits by turning the attention forcibly to some mental or physical effort as soon as the aura is perceived, and attempts of this kind should be diligently encouraged. Occasionally the inhalation of nitrite of amyl will prevent the further development of an attack. When the fit has really begun little can be done in the way of treatment, but the patient can be protected from some of the results of the convulsions. As a rule he must lie where he falls, unless this is in itself a position of danger (a pool of water or the fire), but he can be prevented from injuring himself against surrounding objects; his collar, necktie, cuffs, and other tight bands should be at once loosened; and a piece of cork, gutta-percha, or firewood should be held between the teeth to prevent the tongue being bitten. False teeth worn by an epileptic should always be removed at night, as they may be loosened in a fit and become impacted in the pharynx.

For the *status epilepticus* prompt treatment is necessary, as the patient may die from exhaustion. Sometimes the interval between attacks is such that medicine may be given by the mouth. Chloral hydrate, 30 grains, and potassium bromide, 60 grains, may be given in this way, four-hourly, until the attacks cease. If the patient is unable to take drugs by the mouth paraldehyde, in a dose of 4 to 6 drachms in 6 ounces of water, may be given by the rectum. The proof of absorption may be found in the characteristic odour in the patient's breath. If, as not infrequently happens, the attacks are so frequent as to prevent rectal absorption hypodermics are the only resource. Luminal may now be obtained in ampoules, each containing 1 c.c. of a 20 per cent. solution for subcutaneous or intramuscular injection. One of these may be administered every two or three hours if necessary. As an alternative, hyoscine hydrobromide may be given hypodermically in a dose of $\frac{1}{100}$ grain, repeated two-hourly, but this has the disadvantage of being a respiratory depressant. Post-epileptic confusion may need to be treated with large doses of sedatives, of which paraldehyde, 2 to 4 drachms by the mouth, is the best, or failing this, any of the remedies advised for *status epilepticus*.

Dietetic. Hippocrates gives a list of the various articles of diet forbidden to epileptics by "the conjurors, purificators, mountebanks and charlatans" of his day. Successors have not been wanting. There is no evidence to show that the epileptic is better on one diet than another, with the exception of the ketogenic diet to be described. This is based upon the observation that in patients who are having frequent attacks, ten to twelve days' complete starvation will cause a considerable reduction, and often a cessation, of the seizures. The effect appears to be due to the ketosis resulting from starvation, and a similar effect may be obtained by giving a diet poor in carbohydrate and relatively rich in fat. The basal requirement of protein is calculated by allowing 1 gram of protein per kilogram of body weight. Carbohydrate is cut down to a minimum and the calorie value made up with fat. The results obtained by this method have on the whole been disappointing. Success is more likely to be obtained with children than with adults, and the treatment may be of especial value in a child presenting frequent minor attacks with mental deterioration when other remedies fail. (See diet tables on pp. 474 to 478.)

Infantile Convulsions. These do not differ clinically from the epileptic attacks of other persons with the exception that the disturbance of consciousness which is the main feature of minor attacks is less noticeable at this age.

Ætiology. As in adults the liability to attacks may be due to organic disease or may be of the idiopathic variety. The commonest organic causes of a limited number of attacks are meningitis, particularly tuberculous meningitis and acute encephalitis, but when the series of attacks is prolonged it is necessary to think of injury to the brain at birth, and congenital failure of cortical development. In such cases the liability may disclose itself during the first few days or weeks of life or its appearance may be delayed.

The idiopathic variety frequently discloses itself in infancy, at which age the cortical function appears to be least stable. One or two attacks may occur, perhaps precipitated by teething, prolonged screaming, an acute infection, dyspepsia, or diarrhœa, and for the rest of his lifetime the individual may be free, but in a considerable proportion of cases fits occur later in life, the commonest age of recurrence being at or before puberty. Thus in the personal history of many adult epileptics whose more serious attacks date from childhood or adolescence a history of one or more infantile convulsions is to be obtained, and in the family history of epileptics the story is often obtained of one or more members who had a convulsion or convulsions in infancy without later recurrence.

Treatment. In the past undue importance has been attached to the precipitating causes of infantile attacks. It is probably true of the infant as of the adult that the precipitating factor cannot cause an attack unless the epileptic liability is already present, and that the epileptic liability in infant and adult is of the same nature and requires similar treatment. The occurrence even of a single attack therefore indicates the need for an appropriate dose of bromide, such as 6 grains daily, or whatever is the maximal dose which is quite harmless in its effects, which should be continued regularly for a period of six to twelve months. The duration of this treatment will be guided by the circumstances in which the attack occurred. The attack which occurs without any adequate precipitating cause signifies the greater epileptic liability. In the case of a child who has had a convulsion or convulsions in infancy the possibility of recurrence later should be watched for so that if this occurs treatment may be begun at once. Epilepsy, as Gowers insisted, is a self-perpetuating disease, and the opportunity for successful treatment is greatest after the first attack. When a fit occurs it is usual to place the child at once in a warm bath. If the bowels have not been recently opened, or if there is reason to suppose the ingesta are causing irritation, a grain of calomel may be placed on the tongue. If the fits are very violent and continuous, chloroform may be cautiously administered; 5 grains of potassium bromide may be given, combined with 3 to 5 grains of chloral.

MIGRAINE

(*Megrim, Sick Headache, Hemicrania*)

This complaint consists of recurring attacks of headache, sometimes preceded by certain abnormal sensations, and often associated with nausea and sickness.

Ætiology. The prime cause appears to be a constitutional defect. In a large proportion of cases there is a family history of the disease. The headaches commonly begin about the age of puberty, but inquiry will often elicit a previous history of "bilious attacks" in childhood, and it appears that migraine and the so-called cyclical vomiting of children are closely related. The complaint more rarely develops in later years. Having once appeared, it usually persists throughout adult life, with a tendency for the attacks to diminish in frequency or disappear after the age of fifty. It is rather more frequent in women than in men, and the attacks are sometimes closely related to menstruation. As occasional causes of the attacks many different agencies have been held responsible. Mental strain appears the commonest, and this probably explains the relative frequency of migraine among intellectual workers and persons of an excitable disposition. In a certain number of cases eye-strain, especially that resulting from uncorrected errors of refraction or of muscle balance, may be an important factor. Constipation or dietetic indiscretions may initiate paroxysms. Allergy may perhaps be a cause in some cases. But, as in the case of epilepsy, we must confess that the majority of the attacks occur without apparent cause.

Pathology. No anatomical changes have been found to account for the disease, either in the brain or elsewhere. The nature of the attacks, especially the association of headache, vomiting, slowing of the pulse rate and visual dis-

explanation of these cases is forthcoming. The fact, however, remains that attacks of this nature may continue for twenty to thirty years without the development of any signs of serious organic disease.

Diagnosis. The periodicity of the attacks with intervals of perfect freedom, the age of onset, and the association with nausea are as a rule sufficient for a diagnosis. But in every case other causes must be excluded. The recurrent headaches of cerebral tumour are sooner or later associated with papilloedema or signs of local damage to the brain. Other causes of paroxysmal headache that must be considered are those due to infection of the nasal sinuses, syphilitic meningitis, cerebral arteriosclerosis, and toxic causes such as uræmia.

The aura may be confused with that of epilepsy. But in the latter disease the aura is of momentary duration, while in migraine it occupies about twenty minutes. Nor in migraine is there any disturbance of consciousness. Some patients may be troubled more by the nausea or vomiting than by the headache, and seek relief for these symptoms only.

Prognosis. Under treatment much improvement may be obtained both in the frequency and in the severity of the attacks, though the disease commonly continues for years. It is, however, not dangerous to life, and there is no evidence that sufferers from migraine are more liable than others to hæmorrhage, thrombosis, and other diseases of the brain. The disease often becomes less frequent or disappears altogether after the age of fifty, especially in women after the climacteric.

Treatment. *In the interval.* The patient should be placed under the most favourable hygienic conditions, including a carefully regulated diet, the avoidance of constipation, exercise without exhaustion, pure and bracing air, and exemption from excessive brain study or mental worry. Hurst maintains that many sufferers may be cured of their attacks by the correction with glasses of errors of ocular refraction or muscle balance.

Of drugs the most valuable is luminal. This may be given in tablet form or in a mixture as luminal sodium. Half a grain thrice daily is usually adequate and insufficient to cause drowsiness. It must be taken regularly for many months, and as a rule diminishes both the frequency and severity of the attacks. In some cases Gowers' mixture, containing liq. trinitrini ℥i, liq. strychninæ ℥v, tr. gelsemii ℥x, sodium bromide gr. x, dilute hydrochloric acid ℥x, taken regularly as a preventive, has a good effect.

During the attack. The sufferer usually learns from experience that the less severe attacks can be cut short. Ten or fifteen grains of aspirin and an hour's rest on a sofa in a quiet and darkened room often suffice, especially if during this period sleep can be procured. If the symptoms appear at the end of an exhausting day a good meal and a glass of wine will sometimes clear the air, provided the nausea has not set in. In the more severe attacks there is total cessation of gastric peristalsis (as shown by X-rays), and nothing can be taken by mouth except sips of water. Rest in a darkened room is then the only means of relief. If vomiting is severe and prolonged, rectal infusions of 6 per cent. glucose should be given; they help to cut short the attack and lessen the subsequent exhaustion. Cold applications to the head are usually welcomed. If the pain is unusually severe, morphia should be given hypodermically, and the dose may need to be repeated. If this should be necessary, it must be administered either by the medical attendant or by a trained nurse. The morphia should never be entrusted to the patient or her friends.

MYOCLONUS

(Myoclonia)

Under this title are grouped a large number of conditions, of which the essential feature is short, quick contraction of muscles, not forming part of epilepsy,

hysteria, chorea, athetosis, etc. Myoclonic movements occurring in encephalitis lethargica have already been referred to (*see* p. 706).

PARAMYOCLONUS MULTIPLEX

Friedreich described under this name the case of a man who had sudden lightning-like contractions of the large muscles of the arms, forearms, and thighs. The contractions ceased when he walked, and were worse when he was quiet in bed ; if one arm was used the contractions ceased in it, but continued in the other. The contractions, though violent, produced no movement of the limb as a whole. The knee jerks were increased ; the skin sensibility, muscle sense, and vasomotor and secretory phenomena were normal. The condition disappeared under treatment with galvanism, but it relapsed and persisted till the man's death. Numerous other cases have been recorded of clonic muscular contractions which differ in many points from Friedreich's case. The essential seems to be the occurrence of spontaneous rapid contractions of isolated muscles or parts of muscles in different parts of the body, in some cases the limbs, in others the face and trunk, generally bilateral, but not of necessity equally, or at the same time, on the two sides ; sometimes, but not generally, causing locomotive effect in the parts involved ; occurring at the rate of 60 to 100 in the minute, but quite irregularly ; varying in frequency and force on different days ; and often increased when the patient is under observation, or exposed to external stimuli (sound, touch). The mechanical excitability of the muscles is increased ; their electrical excitability is unchanged. Some cases have been associated with epilepsy (*myoclonus epilepsii*), others have shown close resemblances to hysteria, and it has occurred in two or more members of the same family ; rarely these movements have been associated with definite disease of the central nervous system. The pathology is unknown. Galvanism to the spine, hydropathic treatment, arsenic and chloral have been used to combat it, and recoveries have occurred ; but the prognosis is not good.

THE TICS

(*Habit Spasms*)

A tic has been defined as a co-ordinated, systematised, purposive act, reproducing in an involuntary manner the co-ordinated movements of every-day life (Meige).

The movements usually commence in childhood, between five and twelve years of age, affecting especially the facial muscles, and being frequently repeated at irregular intervals. Such movements are blinking the eyes, twitching of the angle of the nose or mouth, shrugging the shoulders, twitching the fingers, uttering noises or words, kicking out the legs, or other simple movements. They have probably been voluntary, in the first instance, for the purpose of relieving an irritation, or in response to some local sensation, and then have been repeated reflexly, or stimulated by a thought, and finally have become automatic—a bad habit, of which indeed the child may be almost unconscious. The movements may become less under observation, and in the same child one kind of movement may be cured, and after a time another will take its place. It is a question whether certain visceral disorders should not be considered as belonging to the tics, although they are more usually referred to as symptoms of hysteria, and will therefore be described under that heading. Such are certain types of functional vomiting and aerophagy—a condition in which the individual in attempts at retching is continually taking down gulps of air into his stomach.

Movements of a reflex nature arising, in the first place, from peripheral irritation are not perpetuated as tics in persons whose mental adjustment is normal. Thus in children the disorder is frequently associated with bed-wetting, night terrors, and other signs of a neurotic constitution, and the habit probably always

originates at a psychical level as an expression of faulty adjustment of the personality as a whole. In favour of this also is the fact, ascertainable from the patient in most cases, that the movement is preceded by an imperative desire to perform it, and that if this is inhibited great mental distress is occasioned.

The distinction usually has to be made from chorea, in which the movements are, as a rule, more widespread, and are purposeless and irregular.

In the causation two sets of factors have to be considered: on the one hand, neglected sources of peripheral irritation, such as a chronic conjunctivitis or a frayed collar, and difficulties of an emotional nature, such as unhappy domestic surroundings or imperfect adaptation to school life; these are the environmental factors, and, in the phraseology of the old parable, may be called the seed. On the other hand is the neurotic personality which furnishes the soil, and it is upon this latter that the prognosis largely depends. In some cases removal of all sources of irritation, a complete change of environment, and assistance in the solution of personal difficulties may effect a cure, especially in children. In adults and in cases of long standing the disease is likely to be permanent, taking the form in some cases of a mere eccentricity of behaviour. It may be a symptom of deeply rooted mental instability. In the treatment bromides are useful for their sedative effect, together with exercises in which the patient is taught to relax the affected muscles, and to use them for other movements. These exercises may be practised daily in front of a looking-glass, and should be continued as a routine for some time after the abnormal movements have ceased. In addition, attention should be paid to the underlying psychological factors, as already indicated.

SPASMODIC TORTICOLLIS

Besides the temporary affection known as stiff neck or rheumatic torticollis (see p. 555), there are two more lasting conditions known by the name of torticollis: *fixed torticollis*, or congenital wryneck, and *spasmodic torticollis*. The former is due to a permanent shortening of the sterno-mastoid muscle, which is attributed in some cases to injuries during birth, is observed first during childhood, if not in early infancy, and causes asymmetry in the bones of the face.

Spasmodic torticollis, or spasmodic wryneck, is a disorder of function characterised by tonic and clonic contractions of the muscles of the neck, whereby the head is forced into an abnormal position, and it is in many ways allied to the tics.

Ætiology. The disease is rarely seen before the age of thirty; it affects both sexes, but females more often than men. The cause cannot always be ascertained; neurotic inheritance, inflammation of the cervical glands or of the muscles themselves, exposure to cold, falls and injuries, and overstrain of the muscles of the shoulder, arm, or neck in particular occupations, have been recorded as antecedents. Cases have been reported in which the symptom has occurred as a sequel of encephalitis lethargica.

Pathology. Of this little is known. No pathological lesion has been found to account for it, but it presumably depends upon disturbed function of motor centres in the brain or brain-stem.

Symptoms. It begins gradually, being first felt as a mere discomfort in the neck; then distinct jerking movements of the affected muscles are felt, by which the head is rotated or displaced. If, for instance, the right sterno-mastoid is affected, the head is constantly being jerked in the direction of the action of this muscle, the chin is thrust forwards or upwards to the opposite side, and the occiput is drawn down towards the clavicle. The contractions are sudden, irregular, and frequent; for a few moments there is a remission, during which the patient slowly and cautiously tries to bring the head straight, when the

muscle again contracts, and the face is gradually forced round to the left. The movements are for a time checked by supporting the head, and they cease during sleep, but immediately the patient awakes the movements recommence, and continue with but little rest throughout the day; they are generally increased when attention is directed to them. The muscle most frequently affected is the sterno-mastoid, and next to that the upper part of the trapezius and the splenius capitis; the complexus and trachelo-mastoid, the deep rotators of the head, and the platysma myoides are also sometimes concerned. The position of the head is of course determined by the muscles which contract. The sterno-mastoid produces the results already described; the trapezius draws the head backwards and downwards towards its own side, with slight rotation of the face towards the opposite side, while the splenius draws the head downwards with slight rotation towards its own side. Two or more of these muscles may be affected at the same time, most often the sterno-mastoid with the upper part of the trapezius of the same side, or the splenius of the opposite side. An intermediate position of the head will of course be the result. Or corresponding muscles on the two sides may act together, drawing the head backwards during their contraction. In such cases there is generally an associated contraction of the frontal muscles which normally contract when one throws back the head to look upwards. Occasionally the disease itself spreads to the muscles of the face, or to those of the shoulder or arm, especially at the height of the paroxysm; and in rare cases the lumbar or spinal muscles may be affected so that the body is drawn down to one side by the frequent contractions. In slighter cases, or in early stages, there may be no pain, but in severer forms there is neuralgic pain in the contracting muscles. From their excessive action the muscles often hypertrophy; they at least retain their natural bulk. The electrical irritability is normal or increased.

Diagnosis. The constant movements distinguish this disease from congenital wryneck, with its early history and facial asymmetry; from the temporary disorder "stiff neck"; and from spasm of the muscles in caries of the cervical vertebræ.

The **Prognosis** is unfavourable; the spasms may subside after a few months, but far more often persist in a more or less severe form for the rest of life.

Treatment. The disease is most intractable, and numbers of drugs have been tried with but a small amount of success. Those which have been most useful are the bromides, luminal, zinc valerianate, belladonna, and hyoscyne hydrobromide by subcutaneous injection. Opiates and chloroform inhalation check the spasm for a time, but it returns in a few hours unless the dose is repeated. In some cases exercises are of value as described in the treatment of tics, and especially education in the relaxation of the affected muscles.

Many operations have been devised for the treatment of the disease but without much success. In the early stages, if the sterno-mastoid alone is involved, section of the spinal accessory nerve may give relief, and occasionally this may be permanent, but as a rule the spasm appears in other muscles. Foerster, of Breslau, claims success from section of the upper three or four cervical nerve roots, both anterior and posterior, but the operation has so far not met with general acceptance. The disease seems to depend upon a disorder of the higher nerve centres whose tendency to impose spasm will usually find means to assert itself despite obstruction at the periphery.

The symptoms are invariably worse under the influence of mental fatigue and anxiety, and may therefore be improved by means of rest and psychotherapy.

WRITERS' CRAMP AND ALLIED NEUROSES

Those persons whose occupations necessitate complicated movements for long periods of time, such as clerks, pianists, violinists telegraph operators, cigar-

makers, and others, may be subject, when engaged at work, to spasmodic and irregular contraction of the muscles concerned, so that the movement is badly performed and ultimately cannot be effected at all. The exciting cause may be some depressing mental condition, mental anxiety, or business worry; an injury, or local disease of the hand or fingers; but more than all an excessive use of the hand in the occupation concerned.

The disease is most common in those who have a great deal of writing as their daily occupation, such as lawyers' clerks, secretaries, etc. It is hence called *writers' cramp* and *scriveners' palsy*; *graphospasm* and *mogigraphia* have been used as technical terms. This form is naturally more frequent in men than in women, and occurs mostly between the ages of twenty and forty. Gowers pointed out that in the act of writing the pen may be moved across the paper in four different ways: (1) The little finger is fixed on the paper, and the fingers carrying the pen work upon the little finger as a pivot; (2) the wrist is fixed and acts as the pivot; (3) the pivot is at the centre of the forearm, resting perhaps on the edge of the table or desk; (4) all the movements take place from the shoulder. In the first method the movements of the fingers are most complicated and strained, and in the last there may be no finger movements at all. He stated that writers' cramp scarcely ever affects those who employ the last two methods of writing.

Pathology. The cause of this affection is quite obscure. A probable explanation is that it is due to a defect in the centres associated for the act of writing by a morbid lowering of resistance in the commissural connections between the centres, so that there is a radiation of impulses, and so over-action of muscles not necessarily engaged in the act.

Symptoms. The affection generally comes on gradually; it may be felt at first as some degree of aching or strain, which is relieved by ceasing to write. After a time the act of writing is accompanied by a spasmodic tonic contraction of the finger or thumb holding the pen; the finger is pressed firmly on the pen, or it is flexed so as to move up the pen, or it slips off the pen so that the latter is grasped between the fore and middle fingers. The thumb may be similarly affected, or the fingers may be extended or lifted from the paper, or the pen may be driven into the paper, or the hand stops its movements entirely. The attempt to continue writing under these conditions produces a cramped, irregular, angular writing, with thick down-strokes; and after a time the spasm becomes so pronounced as to render the act impossible. This is the *spasmodic* or *spastic* form of Benedikt, which is by far the most common; but sometimes there is tremor of the fingers—*tremulous* form; and a *paralytic* form with fatigue alone has been described, but is quite rare. The spastic form often leads, by the frequent contraction of the muscles, to pains in the hands and wrist, which may after a time become distinctly neuralgic in character; and there is often some tingling or sense of numbness. The spasm may be limited entirely to the act of writing, and other movements, even of a delicate nature, can be performed without difficulty. Sometimes writers' cramp is associated in the same person with spasm on playing the piano or violin, and not infrequently in severe cases some other operation may be at the same time imperfectly performed.

The muscular power is well preserved. There is no wasting, sensory loss or disturbance of reflexes.

The course of the disease is variable. In slight cases treated at once by perfect rest from writing the patient may recover completely; but if he has persevered, forcing himself to write by steadying his hand with the other, or by mechanical contrivances, and has ignored all treatment, the disease is often quite obstinate, and may never be thoroughly cured.

The **Diagnosis** is not generally difficult; writers' cramp at least is not likely to be mistaken for anything else, but it must be remembered that some nervous diseases, such as chorea, hemiplegia, and other paralyses involving power in the

hand, may be first detected in the attempt to write, and may be regarded wrongly as writers' cramp. Nervous people, too, who have obtained some acquaintance with the disease, may easily fancy that a little fatigue is the commencement of it.

Treatment. The first essential is complete rest from writing. In mild cases this is sometimes sufficient to effect a cure in one or two months. Gowers insisted that, on again beginning to write, the patient should learn to write from the shoulder entirely. In more severe cases a much longer rest is required, and if writing is necessary to the patient, he may learn to write with the left hand or use a typewriter. Occasionally, but by no means always, the newly educated left hand also becomes affected. Various devices have been invented, or are improvised by the patients themselves, to save the strain on the muscles of the fingers, such as running the pen through a cork, which gives a larger grasp; or holding a wooden ball in the hand, upon which the pen is fixed at the required angle. Nussbaum's "bracelet" carries the pen, and surrounds the fingers, so that they hold it by muscles (abductors) different from those commonly employed in writing. But, as a rule, these instruments only postpone the time at which complete rest must be taken. A return to the normal action of nerve and muscle may be sought in the use of general tonics, such as iron, quinine, arsenic, and strychnia, and in local treatment, gymnastic exercises, passive manipulations, and massage.

The treatment of the other occupation neuroses must be the same in principle as that already described for writers' cramp.

NEURALGIA

This term is sometimes used for pain, felt in the course of a particular nerve and its branches, for which no organic cause can be found. It therefore describes a symptom rather than a disease. Pain of such distribution may be due (1) to disease of some part of the body supplied by the nerve in question, the pain being, as it were, reflected throughout the whole distribution of the nerve; (2) to disease affecting the nerve fibres either in the peripheral nerves, the posterior nerve roots, or occasionally the grey matter of the spinal cord; (3) to disease of some internal organ whose sensory nerve supply comes from that segment of the spinal cord which corresponds with the superficial distribution of the pain.

As examples of the first cause may be mentioned pain of trigeminal distribution caused by an inflamed tooth; of the second, pain of intercostal distribution due to pressure upon a posterior nerve root from tuberculous caries of the spine; and of the third, the pain along the ulnar border of the left arm experienced in angina.

A common cause of neuralgic pains is a local neuritis the result of trauma, intoxication or infection. In these cases there may be no positive indication, such as muscular wasting or numbness, of actual disease of the nerve concerned. There is, however, usually tenderness to pressure over points where the nerve lies against bone, and the occurrence in some cases of definite signs, such as the loss of ankle jerk in sciatica, makes it highly probable that the others are also due to a localised neuritis. They have already been described. There is, however, one form of neuralgia which, on account of its distinctive features, merits separate description.

TRIGEMINAL NEURALGIA

(Trifacial Neuralgia, Tic Douloureux)

In this affection there are recurrent attacks of paroxysmal pain, referred to the distribution of one or more branches of the fifth nerve. The attacks begin most frequently in the area supplied by the second division, less often in that of the third; the first, or ophthalmic, division is rarely involved, and then only when there is neuralgia of the second division also. In a few cases all three

divisions of the nerve may be affected at the same time. The disease may occur at any period of adult life, but is most common at about the age of fifty. Women are attacked more frequently than men. The ætiology and pathology of true trigeminal neuralgia are at present obscure. It cannot be traced directly to dental sepsis, and may occur in persons who have been edentulous for years. No constant changes are found in the branches of the fifth nerve or in the Gasserian ganglion. Nevertheless the frequency with which the second and third divisions are primarily involved suggests that the disease may be due to the action of bacterial toxins originating from septic foci in the teeth or air sinuses, and reaching the Gasserian ganglion by way of the perineural lymphatics.

As a rule the initial paroxysm is sudden in its onset, and there may be an interval of weeks or months before the next. The intervals, however, gradually become shorter, and the paroxysms more intense, until the patient's life is made intolerable by attacks occurring every few minutes of the day. The pain is extremely severe, and may completely incapacitate the patient while it lasts; it is described as burning, darting or quivering, or as a sensation of red-hot needles being thrust into the cheek. It is often accompanied by a flow of saliva or tears, and there may be flushing of the cheek. The paroxysm is as a rule of brief duration, lasting only a few minutes. During the attack the skin and mucous membranes of the affected area are extremely sensitive, and a breath of cold air upon the cheek, the contact of food with the buccal mucous membrane, or even the movement of talking may suffice to initiate a further paroxysm. In the quiescent intervals, however, and even in the brief remissions between a succession of paroxysms, there is a complete absence of pain or tenderness.

Apart from the paroxysms of pain there are no signs of impairment of the functions of the fifth nerve. The corneal reflex is normal; cutaneous sensibility is preserved; there is no weakness or wasting of the muscles of mastication. By these facts true trigeminal neuralgia may be distinguished from cases of gross organic disease (syphilis or tumour) involving the Gasserian ganglion or its branches.

Treatment. Drugs are of little or no avail; tincture of gelsemium in large doses, combined with bromide, may be tried. The patient will usually discover for herself the advantage of protecting the affected side of the face from cold by means of a shawl or other covering, and may ward off paroxysms by employing writing instead of speech, and taking nourishment through a straw inserted into the opposite corner of the mouth. In skilled hands injection of the nerve roots with alcohol has given good results. The second and third divisions may both be dealt with in this fashion, and relief may often be obtained for as much as a year before the injection has to be repeated. In time, however, this method may fail to give relief, and some more drastic procedure is necessary. The most satisfactory is division of the sensory root of the fifth nerve between the Gasserian ganglion and the pons; this involves a surgical operation of some magnitude, but is more certain than the alternative, which is to inject the Gasserian ganglion with alcohol through the foramen ovale. The disadvantage of either of these procedures is the risk of trophic changes occurring in the eye with subsequent blindness, which is considerable. Most patients, however, will cheerfully take the risk rather than continue to endure the pain.

DISEASES OF MUSCLES

Fibrositis has been described among the chronic rheumatic diseases.

MUSCULAR ATROPHY

Amyotrophy

Atrophy of muscular tissue takes place under a variety of conditions, and has been divided into *simple atrophy* and *degenerative atrophy*. In the former the

muscular fibrillæ diminish in size, while in the latter they diminish in number as well. The two conditions are not entirely distinct in their origin—that is, the same cause may in one case produce the first, and, operating for a longer time or more acutely, may bring about the second, severer form.

Simple atrophy is seen especially after acute or long illnesses, as a result of starvation, some kinds of intoxication, and locally from disuse, and from paralysis in cerebral lesions.

The different forms of arthritis, acute and chronic rheumatism, and gonococcal synovitis, are frequently accompanied by atrophy of the associated muscles; and this may be simple or degenerative. In the slightest degrees only one muscle is affected in the case of each joint; and these are the deltoid for the shoulder joint, the triceps for the elbow, the gluteus maximus for the hip, the extensor cruris for the knee, the pectoralis major for the sterno-clavicular joint, and the flexor brevis for the metacarpo-phalangeal joint of the thumb. In a higher degree of amyotrophy all the muscles connected with the joint are wasted; and in the most severe forms muscles remote from the joint may be involved, as, for instance, those of the whole arm and shoulder in arthritis of the wrist. The cause of arthritic amyotrophy is still obscure, but there are some grounds for thinking that lesions of the anterior grey cornua are determined by the arthritis, and that these cause the muscular wasting (Klippel and Weil). It would thus fall into the myelopathic group.

The degenerative variety is seen in the most pronounced form in the several lesions of the spinal cord and nerves which involve the lower neuron in one or other part, and hence bring about Wallerian degeneration in the periphery. These *myelopathic* and *neuropathic* forms have already been described (see Multiple Neuritis, Progressive Muscular Atrophy, Acute Poliomyelitis, etc.).

PROGRESSIVE MUSCULAR DYSTROPHY

(*Myopathy*)

This is a condition in which there is progressive weakness and wasting of the skeletal muscles in the absence of any local or constitutional cause, and without clinical or pathological evidence of disease of the nervous system.

Ætiology. The cause is unknown, but the disease probably depends upon some congenital abnormality of the muscular fibres. It commonly occurs in several members of the same family, and may be transmitted from one generation to another, usually through the females. Except in the case of the pseudo-hypertrophic form, which is commoner among males, it affects both sexes equally. The first symptoms are developed as a rule during childhood, and are nearly always manifested before the completion of adolescence.

Pathology. The changes are confined to the striated muscles, in which the earliest change appears to be hypertrophy of the fibres with subsequent degeneration, a great increase in the number of sarcolemma nuclei and the deposit of fat in the interstitial tissues. The motor nerves and end plates are intact.

Symptoms. Several clinical varieties of the disease exist, and will presently be described. The features common to all types are the early age of onset and progressive weakness of certain muscle groups. With this may be associated atrophy or pseudo-hypertrophy, but the weakness precedes obvious changes of this kind, and the attention of the parents is usually attracted by clumsiness shown by the child in the performance of certain movements, such as walking or climbing upstairs, by a tendency to fall about, and by difficulty in regaining the erect posture after a fall. The child learns to compensate for the weakness by the acquisition of new methods of muscular co-ordination, and this may result in certain peculiarities of gait and posture, which are somewhat characteristic. The patient has a waddling gait, the feet are widely separated, and the body is thrown from side to side with each step; the gait is further modified by the

produce improvement. Carefully planned gymnastic exercises have done good, and rubbing, massage, and passive movements may be of some use. When the gastrocnemii are so shortened as to prevent the patient standing, the tendons should be divided.

THOMSEN'S DISEASE

(*Congenital Myotonia*)

This disease consists of a peculiar rigidity of the muscles, which comes on whenever they are called into contraction by voluntary impulses after a period of rest. Thus, if the patient wishes to walk and tries to rise from his seat, his muscles become rigid, and he is unable to move; the rigidity lasts a few seconds, and then relaxes so that he can at length get up. His first few steps are attended with the same difficulty, but soon the contractions become more natural, and shortly the trouble ceases altogether, so that he walks with complete freedom and ease. If, however, he should stop for a minute, the muscles become rigid on his beginning to walk again. Quick movements are thus impossible immediately after rest, and sometimes accidents occur, as, for instance, when the patient is descending from a train, and having placed one foot on the ground, he is unable to bring the other out quickly after it, and falls in consequence. Involvement of the muscles of the arms may give rise to a considerable degree of disability in manual workers. After grasping an object firmly, especially if this action is prolonged, the patient is unable to relax his grip sometimes for several minutes. The tendency to rigidity seems to be increased by cold and emotional stress. On inspection there is as a rule no abnormality of the muscles affected, nor is their power diminished. Their excitability to direct mechanical stimulation, however, is altered. When the belly of the muscle is struck with a percussion hammer the resultant contraction, instead of disappearing at once, persists for several seconds. This so-called "myotonic reaction" cannot always be obtained in all the muscles involved, and the ease with which it can be elicited varies from time to time. The closure contraction to strong galvanic currents is much prolonged beyond the time of application, and with continued application of the current a series of contractions has been seen to pass in a wave-like manner from the kathode to the anode. The reactions to faradism are often normal, but may be exaggerated in force and duration. The disease often lasts a very long time, but it may subside.

Ætiology. It happens often early in life, may affect more than one member of a family, and is commonly regarded as being congenital.

Pathology. In a case reported by Dejerine and Sottas, the patient died of nephritis. The muscles were large, protruding, tending to be more globular in shape, of a duller red colour, and less elastic than normally. The number and size of the muscle nuclei were found to be increased; the fibres varied much in size, some being very large indeed, as if swollen. Sometimes the sarcous elements were separated, and the sheath was filled with granules; or the muscle substance was degenerated and vacuolated. The connective tissue was not hypertrophied or fatty, as in pseudo-hypertrophic paralysis. These results agree closely with what had been seen in portions of muscle excised during life. The muscle nerves, nerve trunks, spinal cord, and bulb were healthy.

Treatment. Nothing has been found of use. Thomsen, who suffered from it himself, advised a life of continued activity.

MYOTONIA ATROPHICA

In this disorder stiffness of the muscles similar to that of Thomsen's disease is associated with muscular atrophy. The stiffness, or myotonia, is especially noticed in the inability to relax the flexor muscles after grasping strongly with the hand. The muscles affected by atrophy are the orbicularis oris and orbicularis

palpebrarum (so that there is some resemblance to the Landouzy-Dejerine type of muscular dystrophy), the masseters, temporals, sterno-mastoids (severely), the muscles of the forearm and hands, the vasti femoris, and the anterior tibial and peroneal muscles.

The tendon jerks are frequently absent, although the muscular atrophy is insufficient to account for this symptom.

Outside the nervous system there are other symptoms of a degenerative nature, the most striking being premature baldness, general wasting and loss of weight, and in males atrophy of the testicles with impaired sexual desire. The disease generally begins in middle life and is slowly progressive. It occurs frequently in several members of the same family, as a rule affecting only one generation. It is often associated with cataract, and with a history of cataract in the forebears. Pathologically no constant changes have been found in the nervous system. The muscles show degenerative changes.

AMYOTONIA CONGENITA

(Myatonia Congenita)

In this disease the muscles are extremely flaccid and wanting in tone, and the child lies about in any position and cannot sit up. The condition is noticed at or shortly after birth and may be familial. Later the child is unable to walk; all its actions are feeble, and passive movements at the joints are unusually free. The response of the muscles to faradic excitation is diminished, and the deep reflexes are absent. In many cases there is slow and progressive amelioration, but the majority die of intercurrent affections during childhood. The disease is differentiated from the myopathies by the age of onset, which is, as a rule, earlier, and by the tendency to improvement. The pathology is obscure, but there is some evidence in favour of a congenital arrest of development of the lower motor neurones. Massage, faradism and exercises assist improvement.

FAMILY PERIODIC PARALYSIS

In this curious complaint, the patient suffers from attacks of gradually developing paralysis of the muscles of the trunk and limbs, which lasts on each occasion several hours and then completely passes off.

Ætiology. This disease has also been observed in several members of a family, and is transmitted to the descendants of the sufferers. It affects the two sexes equally, and the first attack has generally occurred between the ages of six and twenty-four.

Symptoms. The paralysis often begins at night. The muscles of the legs, then of the arms, and lastly those of the trunk and neck, gradually lose power, so that in the course of four or five hours the patient is quite unable to move his limbs. The weakness affects first the proximal parts of the limbs, and the distal parts later. The intercostal muscles are weakened, so that the breathing is shallow and feeble; and probably also the diaphragm is involved. The muscles supplied by cranial nerves are generally spared, and the sphincters remain unaffected. The heart may become dilated and the pulse rapid and irregular. The reflexes are gradually lost; and the reactions to both faradic and galvanic currents, which get less and less as the weakness increases, are entirely lost with complete paralysis. Sensation and the mental state are unimpaired. After a few hours improvement begins; the muscles regain power in the reverse order of their loss of it, and after another six to twelve hours power is completely restored as well as the reflexes and electrical reactions.

The attacks at first occur at intervals of months, but they become more frequent until they may occur weekly or oftener; as middle age is reached they again become less frequent.

The **Pathology** is at present obscure. The probability seems to be that some toxin is operating upon the muscular fibres ; and some interesting observations on the relations of the urine and of creatinin excretion to the attacks have been made.

Treatment. Diuresis should be encouraged by salines and mineral waters in order to get rid of toxins.

MYASTHENIA GRAVIS

This is another disease profoundly affecting the action of the muscles ; and in the absence of any constant change in the nerve centres or nerves, while lesions are frequently found in the muscles, it must be regarded for the present as a primary disorder of those structures, probably toxic in origin.

Ætiology. It is slightly more frequent in women than men (142 to 108, Starr) and begins most often between the ages of twenty and thirty, but no age is exempt.

Morbid Anatomy. Several cases have now been examined *post-mortem*. In more than a quarter the thymus has been persistent or enlarged, or the subject of lymphosarcoma ; but in others it has been absent in accordance with normal conditions. In nearly all cases there are found collections of lymphocytes (lymphorrhages) in the muscles, and in some organs such as the thymus, liver, pancreas, kidney and adrenals ; the blood and lymph glands are healthy.

Symptoms. The characteristic feature of the disease is weakness of the voluntary muscles, which are very rapidly exhausted by exertion, but recover their power after rest. In severe cases the weakness persists, and death often results either suddenly or with dyspnœa from respiratory paralysis. The muscles most frequently and generally first involved are those of the eyes, head, and neck, so that the patient has ptosis, diplopia, immobility of the face, difficulty in mastication or in swallowing, defective articulation, nasal quality of the voice with weakness increasing up to aphonia, and inability to support the head upright. But nearly all the muscles in the body may be affected, and in 12 per cent. of the cases it has commenced in the muscles of the limbs ; the patient may be unable to sit up, can only walk a few yards without stopping, or his respiration is impeded, and he has dangerous attacks of dyspnœa. In the limbs the proximal muscles are attacked more often than the distal ; women find their arms tire when doing their hair. The condition is very variable in its intensity, and is aggravated by emotion, by cold, and by the menstrual function in women. The knee jerk is generally active, but may be exhausted by repeated stimulation, sensory symptoms are seldom present, and the sphincters are not affected.

It has recently been shown that the sugar tolerance is low in cases of this disease (5). The affected muscles mostly, but not in every case, react in a special manner to electrical currents—the *myasthenic reaction*. If the faradic current is applied to the muscles, they contract normally, but if it is continued, they soon become exhausted and fail to contract any further. If then the electrodes are removed, the muscle recovers, and then contracts well to the current, again becoming soon exhausted. Contraction to the galvanic current is persistent, and is scarcely at all affected by the length of application.

Temporary improvement may take place, and long remissions have been recorded with relative freedom from the symptoms, but a fatal result generally ensues from respiratory failure or from choking. Forty-five per cent. of the cases collected by Starr died within six months, but many have lived for ten years or more.

Diagnosis. It is likely to be mistaken for hysteria, diphtheritic paralysis, and bulbar paralysis. From the latter it may be distinguished by the absence of atrophy in the muscles, by the myasthenic reaction and the varying degrees of weakness.

Treatment. In 1934 it was discovered by Dr. M. B. Walker that physio-

stigmine given by injection produced an immediate and striking amelioration of symptoms in a case of myasthenia gravis. The observation has now many times been repeated. The most effective drug is prostigmin, which is prepared in a solution containing 0.5 mg. in 1 c.c. From 3 to 5 c.c. of this solution is given by hypodermic injection, together with $\frac{1}{100}$ gr. of atropin sulphate to counteract the slowing of heart action and increased peristalsis otherwise caused by the prostigmin. The effect lasts for a few hours only, so that at present this method of treatment is chiefly of value as a temporary measure to enable the patient to perform a task or eat a meal in comfort, and it is likely to prove of vital importance when the respiratory muscles are in danger from fatigue as the result of intercurrent bronchitis.

Ephedrine hydrochloride, gr. $\frac{1}{2}$, taken thrice daily, appears to give some patients a subjective sense of improvement.

Strychnine appears to improve power and prolong life in some cases (6). Large doses must be given. Hypodermic injections should commence at gr. $\frac{1}{8}$ of strychn. sulph., and may be increased to gr. $\frac{1}{4}$ twice daily. If this has a good effect, it may be continued indefinitely, or equivalent amounts may be given by the mouth.

Respiratory embarrassment should be a signal for absolute rest. A temporary fatigue paralysis of the respiratory muscles may sometimes be overcome by artificial respiration. When the muscles of swallowing are severely involved tube feeding may be necessary.

SOME OTHER DISORDERS OF MUSCLE

In addition to the spasm and paralysis, which are the result of central and peripheral nervous disorders, and which have been described previously, some disorders may be mentioned of which it is perhaps difficult to say whether they are due primarily to failure of nerve or of muscle, or whether they are due sometimes to one and sometimes to the other.

Muscular Exhaustion or Fatigue. The gradually lessening capacity of a muscle to contract as the result of excessive use is generally regarded as being due to the saturation of the muscle with the chemical products of its work, such as sarcolactic acid, extractives, and possibly a special toxin, though it has been also stated that fatigue in the ordinary way is much more largely due to the effect of the poisons upon the nervous centres than to their influence upon the muscles themselves. The actual consumption of the muscular fibre itself in the process cannot be entirely disregarded.

The loss of muscular power after exhausting illnesses and febrile attacks and in advancing years is probably referable to the nervous system as much as to the muscular apparatus.

Fibrillary Contractions (*Fibrillary Tremors*). These have been mentioned among the symptoms of nervous diseases (*see* p. 626). But they occur in conditions of practically normal health. The most common form is a twitching of the orbicularis palpebrarum muscle, causing a slight flickering movement of the eyelid, which is felt by the patient, though it may escape the notice of a bystander. It is sufficiently common to have received the name "live blood" from the public. The same fibrillary contractions occur sometimes in other muscles, such as the deltoid or the biceps. They may be troublesome for an hour or two, or for a few days, and then pass away entirely. Their occurrence is not readily explained, whether they happen in apparent health or in connection with muscular atrophy.

In the latter they are common in the atrophies due to degeneration of anterior horn cells, such as progressive muscular atrophy, and may occur in disease of the peripheral nerves. Of course they cannot take place when the wasting is complete, but only while the degeneration is progressing. If they are dependent directly upon the changes in the anterior cornua of the cord, it must be supposed

that the degenerating cell body sends erratic stimuli to the separate muscular fibrils. Such stimuli are attributed to hyperexcitability, though it is not clear why a degenerating cell should be over-excitable. When occurring in the healthy person, the explanation is even less satisfactory, the little trouble passes away entirely, and nothing remains to show a permanent change in nerve or muscle. There appears to be nothing to show whether it is caused by a temporary or functional change in the nerve-cell or by a primary functional disorder of the muscular fibril.

Fidgets. This appears to be a small matter, but it is of interest in connection with this subject. The condition of physical restlessness, to which the name is popularly given, is often brought on by excessive exertion and consists of a sense of discomfort in the limbs, mostly the lower extremities, which is followed by a contraction of a whole muscle, sudden and sometimes briefly clonic, by which a temporary relief of the discomfort is obtained. The contraction is involuntary and very difficult or impossible to control, and it has the effect of moving the limb to a small extent. The sensation appears to be in the muscle; at any rate, it is deep-seated, and it is not a pain, only the sense of a desire to move. If the contraction is reflex, as it probably is, it may still be that the sensory fibres in the muscle are poisoned by the chemical products of muscular action.

When the "fidgets" occur in these circumstances—but they are not limited to them—they can be generally efficiently treated by massage of the lower extremities, by which it may be supposed the removal of the poison products will be facilitated. A change of position, as, for instance, from recumbent to sitting, will sometimes suffice.

Cramp. This is apparently an involuntary, slow, forcible, prolonged and painful contraction of a muscle, not preceded by any sensation whatever, and only slowly giving way to complete relaxation. It may be repeated at once, or at an interval of some minutes; it may occur only rarely and at long intervals.

This is also a frequent result of over-exertion, and occurs often in bed after a long day's walk, or other continuous effort. Though often spontaneous, it may be induced by a voluntary effort in the muscle affected.

Its exact causation is as difficult to state as is that of the previously described muscular disorders. In the fatigue cramps the influence of muscle poisons is naturally suggested; and this is supported by the well-known occurrence of cramps in certain diseases, such as cholera, choleraic diarrhoea from food-poisoning, and some other exhausting diseases. Poisons are certainly concerned in the cramps of tetanus, of strychnia, of tetany, and of alcoholic or other forms of toxic neuritis. In the first two of these the muscles apparently receive their stimuli from the poisoned spinal cord; in tetany the existence of Chvostek's sign shows that irritation of the peripheral nerves will produce the spasms; but in multiple neuritis it is perhaps not so obvious that the muscles are not set in action by the poison circulating in their own substances as by the change in the nerve trunks. The same may be said for gout and Bright's disease, in which cramps are not infrequent. The spasms of hysteria and the so-called professional cramps (*see* p. 752) are, on the other hand, more clearly central in origin.

The treatment of cramps is not very satisfactory. Where a toxic action can be recognised, the removal or neutralisation of the toxin is obviously the object to be aimed at. When after fatigue or otherwise a single muscle is the subject of cramp, the antagonistic muscle should be at once put into action, so as to stretch the affected muscle, when the spasms will generally give way promptly. For frequently repeated cramps massage may be usefully employed.

MENTAL DISEASES

WE have now to consider the illnesses whose symptoms are due to disturbances at the highest level of bodily integration, that is in the mental processes of the individual. In order to understand the manner in which these disturbances arise it is necessary to know something of the laws governing the mental activities under normal conditions.

PSYCHOLOGICAL PRINCIPLES

Adaptation. Our working hypotheses depend on a conception of living process as an adaptive one ; we assume that each living organism is involved in an unceasing attempt to adapt itself to the external environment and to maintain equilibrium among its own internal arrangements. For the purposes of this adaptation, intricate processes develop in the organism, the most intricate of them being carried out by the nervous system.

If we consider the adaptive process of the organism to be carried out at a series of levels of increasing complexity, then we can regard the purely automatic nervous processes involved in the digestive function, for example, as being at the simplest " vegetative level." The next higher in this series, the sensori-motor or spinal level of adaptive activity, involves the muscles and the co-ordination of their movements by the nerve centres and their connections in the spinal cord ; while in the brain are conducted still more intricate and varying processes of adjustment—the cerebral level. " Above " this again are the most complicated processes of all, namely, those which we call mental. The latter are concerned especially with the adaptation of the whole organism to its whole environment and especially its social environment.

Physiology has not yet succeeded in expressing activity at this level in its own terms, and therefore the language of psychology is the only one available and must be learned if we are to describe the functions of the individual organism at the mental level.

" Levels " of Integration. If in this way we think of an organism as built up in a series of levels of increasing complexity, we get an impression of continuity, mental processes appearing as the most complicated in a series of adaptive processes. In this way we can avoid being perplexed about the particular mode of relation that exists between mental and brain processes ; and we can understand how disorder can arise primarily at any level, so that it is not necessary to presuppose brain disease to explain mental illness. But it is equally clear from this scheme that disorder at one level may upset function at another, so that disorder of brain function may produce disorder of mental function and *vice versâ*.

Emotional Reactions. This is a fruitful idea for the understanding of many physical symptoms which patients present for medical examination and which are not found to have any discoverable physical basis. They are the result of an event at the mental level producing a disturbance at the underlying cerebro-spinal and vegetative levels. For example, the perception of a lion in one's path would normally result in the quickening of the heartbeat, a sensation of discomfort in the epigastrium and perhaps some trembling. Mental happenings associated with these effects are called emotions. For example, those just given are associated with the emotion of fear. It has been much argued whether fear

or any other emotion can exist apart from such physical perturbation. What is certain is that such bodily disturbance may exist apart from any conscious emotion and that, nevertheless, it may be dependent on events at the mental level of complexity. The patient having perceived no lion and being aware of no fear comes to his doctor and asks why he feels ill. One of the discoveries of modern psychology is that something mental may exist without the subject being aware of it, that is, a process at the mental level is not necessarily accompanied by consciousness, or, as is usually said, the process is unconscious, at least for the time being. There are many grounds for this conclusion, but a single example will suffice here. A workman may have injured his back at work and shown no sign of injury afterwards, and yet suffer from general weakness no physical basis for which is discoverable. An exploration of his mind may show that he is *afraid* of returning to his work, perhaps on account of increasing disability for it on account of his age, although he may deny this fear even to himself; that is to say, the fear is not in the realm of consciousness but it is responsible for the feeling of weakness nevertheless.

The effects of emotion on the bodily systems are various and can be conveniently classified as follows:—

Circulatory System. A sudden and severe emotional stimulus may cause temporary cessation of the heart-beat through vagal inhibition. This results in loss of consciousness, and is responsible for the common faint or swoon of emotional origin. Less severe stimulation causes acceleration of the pulse with forcible thumping action of the heart and throbbing of the large vessels. The peripheral arterioles and capillaries, under the influence of severe emotion, may contract, with resultant pallor, but more commonly dilate, the phenomenon of blushing being due to this cause. Except in the cases of severe emotion with vagal inhibition, the blood pressure is raised.

Alimentary System. The secretion of saliva is diminished. There may be spasm of the pharynx and œsophagus. The movements and tone of the stomach and intestines are diminished, there is spasm of the pyloric and ileocolic sphincters. In acute emotion vomiting may occur. Gastric secretion is abolished or reduced. The pelvic colon contracts, and the anal sphincter is relaxed, leading sometimes to evacuation of the bowels.

Respiratory System. The respiratory movements are increased in depth and frequency, and with this there may be a sensation of “suffocation.”

Genito-urinary System. The secretion of urine is increased, and the bladder contracts. This leads to a call to micturition, or in extreme cases there may be involuntary relaxation of the sphincter with incontinence of urine. In males prostatic secretion and emission may occur.

Endocrine Glands and Metabolism. The output of adrenalin is increased, and this in turn may cause further stimulation of the organs innervated by the sympathetic system. The blood sugar is raised, and glycosuria may occur. Metabolism generally is increased.

Nervous System. Besides the mental condition of anxiety, which fills the mind to the exclusion of purposeful thought and of sleep, there may be tremor of the limbs and sensations of numbness. Discomfort or pains in the head are commonly experienced, and are probably due to changes in the cerebral circulation. The pupils are dilated, and the eyes may be protruded.

Skin. The erectors of the hair follicles may be excited, producing the phenomenon commonly described as “goose flesh.” Profuse sweating may occur.

The emotional reaction, if it persists for any length of time, is accompanied by an unusual sense of mental and physical fatigue.

The Conditioned Reflex. Pavlov has shown in animals by means of experiment that a previously indifferent stimulus may become so closely associated with an effective one as itself to become effective. The experiment in which the sound of a bell was in this way converted into a stimulus to the salivary reflex

is familiar to students of physiology. In the same way an indifferent stimulus may through association become capable of producing the emotional reaction.

The association may be produced either by frequent repetition or by the coincidence of particular circumstances with an especially severe emotional reaction. Many examples might be quoted of such an association leading to a conditioned emotional reaction. During the recent war men who had been exposed for long periods to occasional shell-fire would afterwards exhibit tremor and palpitation at any loud and unexpected noise. A woman who was summoned to the telephone to hear that her husband had been killed suffered for several months afterwards from a sensation of extreme anxiety and palpitation whenever she was called to the instrument.

Similar emotional disturbances may be experienced by a man who has met with an accident while driving a motor car when next he takes the wheel, even though he is an experienced driver and the road is clear. Such associations are usually lost with further experience in the same way as the simpler conditioned reflexes established in animals can be broken down by lack of "reinforcement."

Mental Integration. Hughlings Jackson's concept of levels in the nervous system is one that can be extended, by analogy, to the internal arrangements of the mental level. And here also, as in the nervous system, the "layering" is largely of historical origin. The uppermost layer of the mental level is, in Hughlings Jackson's phrase, the last acquired, the most complex and the least organised. The lowest levels are those of infantile experience. Between, as it were, is all that has been experienced in the course of life. But it is necessary to postulate also for the organism a phylogenetic endowment with instincts, which underlie even the infantile experiences.

Release. This analogy enables us to think in terms of another of Hughlings Jackson's concepts—that of "release phenomena." The abrogation by the higher levels of their function will allow, earlier, more primitive reactions to occur. This is perhaps most easily seen in alcoholic intoxication, which sometimes has the effect of uncovering unexpected trends. A similar release can also occur from the operation of purely psychological factors.

Consciousness is the quality that appertains to that mental function which is for the moment the one most concerned with adaptation.

Unconscious "Mental" Events. The other mental experiences exist in a form which can sometimes be revived in consciousness with effort. But the constitutional endowment, that is the instincts, since they are not individual experience but only the forces behind it, remain outside of consciousness or "unconscious." We shall see that there are other reasons than never-having-been-conscious for mental experiences remaining away from consciousness. It has to be remembered also that the so-called instincts are not entities so much as abstract concepts to cover a great many phenomena which are not explicable as the result of acquired experience. These phenomena are mainly divisible into classes, those associated with self-assertion or self-preservation, and those associated with reproduction or the preservation of the race.

It has to be noted that adaptation has two aspects: it has to face two ways. There is adaptation to circumstances without and adaptation to instinctual urges from within. We therefore have a concept of the adaptive function in the individual operating as it were between two forces, the environmental stimuli and the stimuli from within (the tendencies initiated by instinctive forces), and it has to preserve a balance between them. This adaptive function must clearly be intimately connected with what is called the self, or, in technical terms, the ego.

The environmental stimuli include all experience; what makes them important for adaptation at the highest or mental level is their personal quality. That type of adaptation, failure of which leads to the appearance of symptoms of a mental disorder, is always a matter of personal relationships. One does not get a nervous illness merely because one has seen or heard something, but only if it

has some particular meaning for oneself in relation to the other persons in the environment. The important persons are especially other people in the family or those who might be regarded as their substitutes, such as nurses, etc., companions, lovers, teachers and the like. These might all be classed as environmental stimuli, while the inner stimuli are the instinctual urges principally concerned either with self-assertion, *e.g.* social ambition, or with sexual satisfaction (in the full sense and not in the sense of merely physical satisfaction).

Conflict. An important consequence of this complication of arrangements is the possibility of conflict, especially between the environmental demands, the instinctual urges on the one hand, and what are conceived to be the wishes of other persons on the other. Conflict of this sort may result either (*a*) in complete repression of one side or other of the contending forces, in which case there are no symptoms, or (*b*) both forces may continue to contend for dominance, with the result that symptoms are produced in the form of signs of disturbance at one or all levels. There may then be partial repression with the result that at the conscious level there appear evidences, usually distorted and disguised, of the conflict that has been repressed. These evidences constitute symptoms; for example, depression and anxiety, phobias delusions, and the like.

Repression therefore means, if successful, a complete blotting out of the repressed tendencies from consciousness. If repression is only partially successful these tendencies appear in consciousness in a disguised form. The simplest example of disguise is the repression of a desire (forbidden by conscience, *q.v.*) and its substituted appearance in consciousness as a fear. Sometimes repression has the curious effect of making both sides of the conflict unconscious, with the result that that part of the individual's mental experience is no longer accessible to his consciousness and he develops an amnesia which may cover anything from a small period up to the individual's entire life.

So we see that there are items of a mental order which are unconscious because repressed, in addition to those that have never been conscious at all (instincts) and, in addition, to those which can be recalled at will.

What does the repressing? An analogy from the lower levels of the nervous system, *i.e.* a physiological analogy, will help to make clear one type of repression—for clearly where there are two parties to a conflict and one of them is repressed, the other holding the conscious field, you get something analogous to inhibition. One of the contending parties is nearly always the ego or self, which will often wilfully repress some unpalatable fact, that is, unpalatable to the ideal that the ego has shaped for itself. Another closely allied contending element is the "conscience," which is a kind of mental precipitate of the injunctions and prohibitions conceived by the ego to be laid down by the environment, especially the parents. This kind of conscience therefore is a mental structure deeply rooted in the individual history, and for that reason alone functions largely automatically and unconsciously. It often is responsible for the feelings of inferiority and guilt which are so common in neurotic personalities.

This tendency for a man to remain unconscious of his own emotions if they are of a repellent nature is of great importance in causation. Thus, for instance, in the recent war a man whose training had taught him to regard the emotion of fear as tantamount to cowardice would sometimes remain oblivious to the presence of this emotion within himself. The emotional reaction would then be present without cognisance of the emotion, and the individual would be driven to explain the phenomena of palpitation, sweating and so on as evidence of bodily disease.

Furthermore, he might be led by his fear to evade his duty without being conscious of the motive which impelled him. Physical disease under such circumstances offered a way of escape, and in this state of mind a man would, in the face of all reasonable considerations, accept the least suggestion of bodily disability.

A blow on the arm with temporary numbness would suggest the idea of paralysis of the limb. This idea, exerting by means of the unconscious motive a strong positive influence, would keep attention fixed upon it; all evidence to the contrary would for a similar reason be excluded from conscious attention, so that in a short while the paralysis of the arm became a fixed belief.

Many of the phenomena of daily life depend upon the influence of unconscious motives in directing attention towards certain aspects of self and environment and away from others. Men are notoriously blind to their own faults. They tend to remember their virtues and successes, to forget their failures and peccadilloes. Many acts of forgetting depend upon such a cause.

The man who is being influenced in his actions or his judgments by an unconscious motive is usually ready to defend his position upon logical grounds. His arguments, however plausible, prove on analysis to be fallacious. They are in fact further products of the hidden motive, and to distinguish them from processes of true reasoning they are called by psychologists "rationalisations" (4).

With these principles of adaptation, integration of levels, emotional reactions, unconscious mental events, repression, and conflict we are in a position to understand the main phenomena of psychological illness.

CLASSIFICATION

Psychiatric classification is particularly difficult and particularly misleading. Every "case" is an individual and not a disease. The disease is the individual. The essential thing is to understand the patient and not to classify him. His mental condition can only be understood by taking account of the patient's history and situation in all practicable ways. To place him in a class is only permissible for the purpose of making certain rapid conclusions of a safeguarding, therapeutic and prognostic kind. The following classifications may be used, but there is no hard and fast line between many of the groups: (1) Psychoneuroses; (2) affective reaction-types; (3) schizophrenic reaction types (dementia præcox); (4) paranoic and paranoid reaction types; (5) organic reaction types; (6) epilepsy; (7) psychopathic reaction types; (8) mental deficiency. Groups 2, 3, 4, 5, 6 and 7 constitute what are known as the "psychoses," to distinguish them from the mental deficiency (Group 8) and the psychoneuroses (Group 1). Mentally defective persons may, of course, develop a psychosis or a psychoneurosis (5).

Broadly speaking, mental disorders can be divided into those which are dependent upon detectable organic disease of the brain (blastophoric, degenerative, inflammatory, neoplastic or toxic) and those which are not. In the former class the defects found are principally, but not entirely, in the sensorial field (*i.e.* in perception, comprehension and memory); in the latter the positive findings are mainly, but not always or entirely, in the fields of behaviour, affect (or emotion) and thought content.

Brief clinical definitions of these principal types of mental disorder are given here in a preliminary form:

(1) **Psychoneuroses.** The psychoneuroses involve as a rule much less disturbance of the personality than the other groups. It is much more usual for a patient suffering from a psychoneurosis to go about his daily business than it is for a person with a psychosis; a psychoneurosis usually betrays to the casual bystander no sign of its presence; a psychosis commonly does so. There is no misconstruction of reality by the psychoneurotic. The psychotic, on the other hand, commonly suffers from delusions or hallucinations, or at least from a feeling that the outside world has changed. The commonest psychoneurotic disorders are complaints of fatigue, headache, pains and paræsthesiæ of all kinds, morbid fears, paralysis, tremors and tics, disturbances of memory

(usually patchy) and disturbances of consciousness such as somnambulism and fugues.

(2) **The Affective Reaction Types.** The chief clinical characteristic is the *disorder of mood or affect*, with which the other symptoms more or less conform. Thus in the manic condition there is excessive happiness (*elation*) with much *restlessness* (often of a playful kind) and a *flight of ideas*, with punning and rhyming. In the depressed condition there is *sadness*, with slowing of speech and action ("*retardation*"), and often also gloomy delusions of personal unworthiness and guilt and of the ruin of family and affairs.

Involucional melancholia is a type of depression occurring chiefly, but not exclusively, at the involucional-period of life, and characterised by sadness, but with restlessness rather than retardation, much apprehension, and nihilistic and hypochondriacal ideas.

(3) **The Schizophrenic Reaction Types.** The characteristic features of these are the more or less pronounced *lack of contact with the environment* and the *internal inconsistencies* in the clinical picture. The patient is seclusive and apathetic, living in a world of his own, while his speech is more or less incoherent and his mood and his thought often do not harmonise. There are erratic and impulsive or fantastic conduct, absurd delusions, hallucinations, chiefly auditory, and feelings of influence.

The differentiation of sub-types within this syndrome is artificial, as most cases show features belonging to several of the sub-types. The most distinct of these subdivisions is the catatonic, in which there is stupor and resistiveness alternating with wild impulsive excitement.

(4) **Paranoia and Paranoid States.** In these conditions more or less systematised *delusions of persecution* or, more rarely, of grandeur are the prominent symptoms. There is no apparent affective or intellectual disorder, the delusions being fairly consistent within themselves, so that if certain premises were granted the delusions would more or less reasonably follow.

Paraphrenia is artificially distinguished from paranoia by the presence of *hallucinations* in the former. On the whole, it has become customary to designate as paraphrenic those cases in which the delusions are not well systematised, in which hallucinations are prominent, and the general personality undergoes more deterioration than in paranoia. Paraphrenia therefore stands nosologically between paranoia and paranoid schizophrenia.

(5) **Organic Reaction Types** are the result of toxins, infections and nerve-degenerative processes; they are especially characterised by *impairment of the intellectual functions*, especially memory and comprehension, leading to defects of orientation and of attention. The severity of the condition is apt to fluctuate—the so-called *mental tension defect*. In the acute form of organic reaction—delirium—there are in addition usually hallucinations. Mood disorders also occur, *e.g.* fear in delirium, and based on the latter and on the intellectual disorder, changes in conduct take place, so that the whole personality is impaired, at least in the chronic forms.

(6) **Epilepsy.** The most important clinical feature is the occurrence of fits, major or minor, but there is also in some cases an epileptic change in character which exists in the interparoxysmal period and may at times or continually constitute a more or less severe disorder in itself. The epileptic character is typically selfish, childish and religious, with no real depth of feeling, and with, in many cases, *intellectual* defects of attention, comprehension and memory. There are also episodic disturbances in the form of *depression*, *irritability*, *excitement* and *ecstasy*, and in the period immediately after the fit *automatic actions*, which sometimes take the form of physical violence or other anti-social acts such as blatant thieving and indecent exposure. The general account of epilepsy has already been given.

(7) **Psychopathic Reaction Types.** In these conditions the prominent

feature is a nearly lifelong emotional instability, which leads to erratic, anti-social, or impulsive conduct at times. Mental disorders of the other types appear readily in these patients, and as readily disappear.

(8) **Mental Deficiency.** This group comprises all individuals who from birth or from an early age have suffered from intellectual deficiency, as defined in the Mental Deficiency Acts of 1913 and 1927.

METHODS OF PSYCHIATRIC EXAMINATION

Since mental disorder in the full sense of the term is a defect of social adaptation, and since a medical examination is but one of the numerous social situations to which the patient has to try to adapt himself, it follows that the examining physician may have the opportunity of seeing only a portion of the patient's symptoms; therefore he must take careful account of all the information that may be obtainable from other sources and from observers in other circumstances (home, school, companions and the like). In this there is a difference of degree from what occurs in general medicine, where symptoms and signs are elicitable either at the time of examination or by direct questioning of the patient. With psychiatric patients it not infrequently happens that very little that is clearly abnormal is to be detected at an interview. The patient's abnormal behaviour may be reserved for special circumstances, as in the naughty child who is a tyrant at home and an angel at school. On the other hand, the signs of mental disorder are often as definite as the signs of physical disease, if one knows how to elicit them. The following scheme provides an orderly system of examination; the results when applied to any patient can be tabulated at the end and deductions made from them.

Perhaps the most important function of the examination is to get the patient to talk. Specific questions are to be regarded either as short cuts (not to be resorted to except when the patient's spontaneous talk may cease to be helpful) or as organised methods of getting the patient to speak along the lines known by experience to be the most fruitful for reaching conclusions.

The following outline is intended to cover almost any type of mental case. It is more uniformly detailed than is necessary in the individual instance; only experience will teach what facts to lay stress on in a given instance.

HISTORY OF THE CASE

Complaints. It is necessary to start by getting a list of the patient's complaints from the patient himself or, in the case of an unco-operative patient, from the relatives or friends. The latter should always be carefully interviewed: their account may be very different from that of the patient, and the discrepancies are themselves illuminating. It is necessary not to be prejudiced beforehand by the notion that the relatives' account must necessarily be more reliable than that of the patient. Particular topics that should be inquired into when there is any reason to suspect such abnormalities are suicidal attempts, exhibition of temper or violence, alcoholism, idleness, tendency to lie long in bed and the like. These usually are more readily acquired from the relatives than from the patient.

History of Present Illness. The history of the present illness should be obtained in careful chronological order from the patient himself if possible. It is a good rule in psychological medicine to distrust the ostensible beginning of the illness and to seek for incidents further back. Very frequently a condition that is said to have begun suddenly has had prodromal symptoms of long standing. In particular the setting of the onset of the present illness is extremely important. The possibilities of precipitating factors actually in the home, at business, in the

financial circumstances and in personal relationships, have to be borne carefully in mind.

Personal History. For these and other reasons, an adequate account of the personal history is very necessary. Inquiries may be made systematically under the following heads :

(A) *Pre-natal conditions* include the health, habits and social circumstances of the family at the time of conception and gestation (alcohol, drugs, syphilis, tuberculosis, and chronic diseases generally of the parent).

(B) *Conditions at birth* are such as the character of the labour (prolonged, instrumental, complicated, premature), the occurrence of an unusual amount of asphyxia or of actual injury to the skull. (A) and (B) are more apt to give relevant information in cases of primary mental defect.

(C) *Native endowment and post-natal development.*

(I.) *Physical.* Inquiry should be made as to the general health, whether healthy or sickly in childhood, and later what specific diseases the patient has had, and what amount of attention the patient paid to his physical condition (including unusual maternal concern about illness, dietetic and other fads). Inquiry should also be directed to the general development—the time of teething, walking, talking, control of the sphincters (bed-wetting), age of puberty and habit and amount of sleep ; and to the general habits of action—whether the patient was lively or placid, active or sluggish, energetic or lazy. Nervous phenomena should be searched for in detail—convulsions, local spasms, tics (head-rolling or nodding, nose-picking, nail-biting), excessive crying or screaming, sleep-walking, sleeplessness and fears of the dark.

(II.) *Intellectual.* This should include the school record, giving the class and age at leaving, and the general attainment and any proficiency or deficiency in special subjects. The after-school education should be noted, especially in relation to opportunity and desire for it. Adult intelligence is displayed principally in foresight, planning, ability to concentrate, and in the kinds of interest (literary, scientific, artistic, etc.). Where there is any suspicion of backwardness, an intelligence rating should be done. (The Terman modification of the Binet-Simon scale, adapted for British children, is the most convenient. The necessary forms are published by G. Harrap & Sons, but the method gives reliable results only in the hands of those accustomed to use it.)

(III.) *Emotional.* Emotional reactions, which the patient may have shown conspicuously in childhood and later, are best inquired for specifically. Was he timid, anxious, happy or serious, moody or placid, or given to worry ? Did he have temper outbursts ? Was he easily depressed or easily elated ? Did he have any unusually intense interests, *e.g.* in religion ? Was he suggestible ? These are subjects which naturally have to be approached very carefully and are usually best inquired for piecemeal in the course of increasing acquaintance with the patient.

(IV.) *Psychosexual.* Where the case seems to demand it, some of the following inquiries should be made, but with the utmost tact. The source and nature of sex information as first acquired and later should be ascertained, as well as early evidences of sexual curiosity, the time during which masturbation was indulged in, whether the patient was frank or prudish, the presence of any perversions, the attitude to the same and the opposite sex, as shown by attachments, love affairs and their outcome, attitude to marriage and reasons for celibacy.

(V.) *Economic.* The degree of economic independence achieved by the patient is important. The jobs held, the reasons for changing from one to another, the general efficiency in them, and the remuneration, give a useful objective basis for estimating the degree of success obtained in general social adaptation.

(VI.) *Social.* The family environment is of great importance. The disposition of both parents should be ascertained as nearly as possible, and that of

brothers and sisters with whom the patient was closely associated. Preferences for one or another on the patient's part are to be inquired for. The type of school and the patient's ability to get on with others—teachers, employers, companions—are important topics.

Personality. From the data thus obtained of the patient's history previous to his illness an opinion may be formed of his development as an individual and as a member of society. We learn what his handicaps were, and with what success he met them, as well as what disadvantages he possessed and what use he made of them. There emerges not only the history of the patient, but a conception of his "personality" as well. "Personality" is an important notion in psychiatry. It denotes not the mere additive product of an individual's traits of character and temperament, but their integration into a working whole. It has been found that there is often a specific relationship between an individual's personality and the type of mental illness he develops. The most frequent and clear-cut types of personality are the syntonie or cyclothymic, the schizoid, the paranoid, the hysteric or mythomantic, and (of disputed significance) the epileptic. Moreover, it has been observed that the progress of most cases of mental illness depends to a considerable extent on the personality that the patient possessed before the outbreak of symptoms: the better psychical stuff the patient is made of, the more likely is he to make a good recovery, just as in diseases of the body the constitutional resistance matters a great deal. Hence it is very important to know how the patient dealt with the various problems that life presented to him before his illness—whether he met his difficulties in a straightforward, determined way, or was shirking, timid, shy, or sensitive, or was readily depressed and worried; whether he tended to blame others rather than himself when things went wrong, or resorted overmuch to day-dreaming instead of working; and whether he (or she) made the most of his aches and pains, or was given to exaggerated self-display in other directions. These are only a few of the numerous lines of inquiry that will furnish clues not only for understanding the patient as a human being, but for grasping the significance of many of the symptoms. Such inquiries are naturally much more important in the preponderatingly "endogenous" variety of psychosis (developing more from within the personality), *e.g.* paranoia, than in those resulting from the incidence of traumata from without (as in infections, *e.g.* syphilis producing general paralysis).

MENTAL EXAMINATION

(I.) **General Demeanour.** This is to be obtained from direct observation of the patient. The following points should be noted: (1) *Facial expression*, manifesting or lacking expression, as sad, uneasy, anxious or afraid, or happy, elated, beatific or ecstatic, or dull, unresponsive, immobile or mask-like. (2) *Dress*. Some patients are careless and untidy; others are over-elaborate or fantastic in their dress. (3) *General activity*. Some patients are under-active and may, in addition, show slowness in movement (retardation). Others are over-active (psychomotor excitement), which is usually an expression of the prevailing mood, *e.g.* wringing of hands in apprehension. Many patients show bizarre or peculiar activity, such as stereotyped movements and attitudes, echopraxia (automatic imitation of what he sees others do), mannerisms, *flexibilitas cerea* (waxy flexibility, the patient's limbs remaining indefinitely in any position in which they are placed by the examiner). Local disorders of activity, as tic or tremor, rigidity, paralysis or abnormal gait, should also be noted. (4) *Speech* (including stream of talk and disorders of articulation (dysarthria) and aphasic disorders). It is important to take verbatim samples, especially of the spontaneous utterances. (a) In his talk the patient may pass rapidly from one topic to another by apparently superficial association ("flight of ideas"), or there may be mere pressure of talk (much talk but no rapid change of topic), circumstantiality (too much detail, like Mrs. Nickleby), retardation (slowing) or blocking

(sudden interruption from within), and all degrees of disconnection up to "a word-salad," or "verbigation"—a superficially meaningless concatenation of words, usually substantives. (b) Mutism (absence of both articulate and whispered speech), with or without ability to write, occurs in some patients, especially as part of a stupor (failure to respond to any stimuli whatsoever). (c) Articulation disorder occurs as mannered intonation in, *e.g.* fantastic paranoics, or as slurring and syllable-stumbling in general paralysis. (d) Aphasic disorders, if present, require special investigation by the methods described in the neurological section. (e) Writing. A sample of this should always be taken as part of the neurological examination, but in the absence of spoken speech it is sometimes possible to obtain information in writing, which then becomes of the highest importance. Inability to write may be associated with absence or defect of speech (*i.*) without organic lesion as *mutism*, depending on the patient's belief that he ought not to or cannot speak, or *aphonia*, depending on a functional paralysis of the vocal cords; (*ii.*) with organic lesion, when the writing difficulty is part of an aphasic or dysarthric disorder.

(II.) **Extent of co-operation** with the environment (*rapport*). The degree of co-operation is most important from the aspects of medical examination, treatment and general handling, and prognosis. Some patients refuse to eat, others to take medicine; some will not see a doctor, others refuse to go to hospital. Mental patients differ from most others in that many of them will not admit that they are ill in any sense.

(III.) **The patient's own story** of the events leading up to his present condition is of the utmost importance. The patient should be encouraged to give his own account. This may be done spontaneously (when verbatim samples will already have been secured) and require only occasional interpolation of a question, or it may be given only in answer to questions, beginning with the simplest (and making verbatim notes), *e.g.* "What is your name? your occupation?" The patient's attention may be obtained only on reiteration of the same question (in preoccupation and in some organic conditions). The relevance of the answers should be observed.

(IV.) **Activity**, subjectively described (the objective data being obtained from Section (I.)). "Can you do things as well as formerly?" (feeling of insufficiency). "Have you difficulty in beginning to do things?" (initial retardation). "Have you felt able for your work?" The questions must be varied to suit the case. The above might only succeed in irritating an over-active elated patient, who may be asked if his work comes very easily to him, etc.

(V.) **Affective status (mood)** is gauged in the following ways:—

(a) From observation of the *facies* and *behaviour*.

(b) *Spontaneous account* of, *e.g.* happiness, fear, depression (often expressed directly as "downhearted," "miserable," or indirectly as "lack of interest," etc.). It is usually necessary, however, to resort to direct inquiry. The language of the emotions is sadly wanting, and few patients have the gift of describing their affective condition, even when descriptive words are supplied to them.

(c) *Direct Inquiry*. It is best to begin with general questions, as "How do you feel?" "What mood are you in?" "How are your spirits?" If these do not elicit a satisfactory statement it is useful to enumerate a variety of words descriptive of mood to enable the patient to choose the appropriate one. Thus: "Are you sad, or happy, or afraid, or anxious?" The degree of the patient's insight into (realisation of) the abnormality of his affective condition is important. "Why are you depressed" (anxious), "etc.?" "Is your depression justified?" Depressive moods in particular are accompanied by inability to have emotional response to or to enter into the feelings of others. This may distress the patient, and may be his chief complaint. A *feeling of unreality* may result when the patient *knows* that things are real, but on account of his own lack of emotional response cannot *feel* that they are.

(d) *Affective or Mood Fluctuations.* There are often exacerbations of a given affective condition from time to time. Depressed patients usually feel worse in the mornings. Anxiety often occurs in attacks. Variation in the depth of depression may be so great that there may be periods of a few hours, especially in the evenings, when the patient feels and looks almost normal. This variation can be very deceptive unless one is constantly on one's guard.

Laughing or weeping may occur with undue readiness, and may be appropriate to the prevailing affect, as in manic excitement, or a depression, although often the depressed patient, for example, complains that he cannot weep; or may take place inappropriately, *i.e.* without corresponding affect or in the presence of a situation calling for a different type of emotional response. This may be accompanied by insight, as in certain organic (especially arteriosclerotic) conditions. In other cases (psychogenic dissociation, as in schizophrenia) there is no apparent realisation of the discrepancy.

Specific reactive tendencies arising from the affective condition are of great practical import from the points of view of care and treatment.

Suicidal wishes or actual attempts, usually in a setting of depression, aggressive acts (homicidal) or tendencies in panics of fear or in morbid anger or in persecuted states, should be very carefully inquired for both from the patient and from his friends. It is much better that a depressed patient should ventilate his suicidal ideas than that the physician, from a false notion that he may suggest them, should not inquire and consequently remain in greater uncertainty than is necessary.

The congruity or otherwise of thought-content and mood must be estimated from a consideration of this section and Section (VI.). Apparent incongruity suggests a serious type of disorder (schizophrenia). For example, a patient may have the most disturbing kind of thoughts, the most vilely threatening hallucinations, and yet appear unmoved; or may hear sad news, as of the death of a relative, and either display indifference or giggle immoderately.

(VI.) **Thought** includes the subjective experience of thinking and the *form* of thinking, which must be distinguished from its *content*: the latter is what the patient says; the former is how he says it.

(a) *Subjective Experience.* "Is thinking easier or more difficult, faster or slower, than formerly? Can you concentrate?" Inability to concentrate may result from an attention defect (*v. infra*), as in the organic type of mental reaction. A simple and useful test of the capacity to sustain a train of thought is the patient's ability to subtract 7 successively from 100 till there is no remainder. Lack of concentration is more commonly the result of absorption of attention in personal concerns—worry, etc.

(b) *Form.* Change in the form of thought is deduced from the talk of the patient. All degrees of disconnection may exist up to incoherence. Also the patient may attach symbolic meanings of his own to ordinary words, or he may invent new words (neologisms).

(c) *Content.* General inquiries include such questions as "Do you worry about anything?" "About what?" "Have you had any unusual experiences?" "Have you felt as if people were watching you or talking about you?" (ideas of reference). Persecutory (delusional) trends should be inquired for, at first in an indirect way. "Does any one treat you badly?" "Is there a concerted plan in this?" "What makes you think so?" A grandiose trend, if present, usually appears readily in the course of conversation. If it does not, and is suspected, it may be sought with such special questions as one's knowledge of the individual case may suggest. Delusions of unworthiness or of sin usually appear spontaneously, but if not, and they are suspected, they can be brought out in appropriate cases by asking the patient whether he feels he has done wrong, and in what way. Hypochondriacal delusions are revealed in the investigation of the physical state, in which the patient should always be questioned regarding the functions of his

bodily systems. Anxiety about physical illness, or the possibility of it, should be carefully distinguished from the more or less settled (and usually unfounded) conviction of disease in hypochondriasis. This has to be done from the manner of statement, the amount of reassurance possible, and the affective setting.

Feelings of influence or passivity may find expression in curious acts or bodily attitudes, or may be revealed only in questioning. "Do you do anything queer or strange?" "Why do you do so?" "Why do you do this?" (naming some unexplained act). "Do thoughts come into your head that do not belong to you?" (autochthonous ideas). "Have you ever had the feeling of being hypnotised or of mind-reading, of hearing your own thoughts or those of others?" Hallucinatory experiences may be betrayed by such acts of the patient as his assumption of a listening attitude, mumbling, gesticulating, sudden or maintained silence and impulsive episodes. More often they have to be inquired for in a general way, as "Have you any peculiar thoughts?" "Do you hear voices?" The presence of auditory hallucinations leads to the questions "Are they noises or voices which you hear?" "Real voices or only your thoughts?" (pseudo-hallucinations). "What do they say?" Visual hallucinations: "What do you see?" "Are they real or only a vision?" "Are they small" (Lilliputian) "or coloured?" "Are they to one side or another?" (hemianopic hallucinations). Hallucinations of taste, smell and hearing should also be inquired for. It is important to know whether any of the sense-deceptions are illusions and whether they depend on local disease (of the sense-organ involved) or, as is sometimes the case, on disease elsewhere affecting the sense-organ reflexly. Organic misinterpretations are more probably of illusory than hallucinatory nature, although some experiences, such as that of "a voice coming from the stomach," are difficult to interpret as based on disordered organic sensation.

(VII.) **Orientation** as to person, place and time.—"What is your name?" "What is my name? my occupation?" "What place is this?" "What is to-day's date?" and if the latter elicits an indefinite reply, "What month is it? what year?"

(VIII.) **Memory** should be tested for inconsistencies or actual blanks.

(a) *Personal Events* (i.). Remote. "When born? and where?" "How old does that make you?" Age of beginning and leaving school, dates of changing jobs, of marriage, births of children, etc., should be asked for where the power of memory is under suspicion. Some or all of these will have been answered in the personal history given by the patient. (ii.) Recent. The patient's account of the chronological development of his illness will have furnished hints under this head. The dates can be checked from the story of the patient's friends. "Since when has there been a change in you?" "How did you come here? With whom?" "What meals have you had to-day?" "Where were you yesterday?"

(b) *Formal Tests of very Recent Memory*. (i.) Ask the patient to remember three things: an address, *e.g.* 315, Bond Street; a part of the body, *e.g.* a finger; and a vegetable, *e.g.* a carrot. Read them over to him once and have him repeat them. Tell him you will ask for them again in five minutes. (These five minutes may be occupied with other questions and this fact noted.) If at the end of that time he is unable to reproduce them on demand, another similar test should be given and the results noted. (ii.) The span of immediate memory may be tested by the number of disconnected digits, letters or words the patient can retain. The lower limits of normal retention are six digits, six letters, and five words. For example, six digits should be read to him at the rate of one per second, *e.g.* 485736. If he succeeds more should be tried; if he fails, fewer.

(c) *Rote Memory*. Ask him to repeat the alphabet, the months of the year, the Lord's Prayer, and to count from 1 up to 20.

(IX.) **Attention**. (a) This may be gauged from general observation during examination. Any tendency to spontaneous fluctuation should be noted.

(b) Special tests may be used where there is a doubt as to the continuity of attention, *e.g.* in certain organic conditions if sufficient co-operation can be obtained.

(X.) **Apperception.** The patient is asked to read aloud a test story, such as the following, which is given to him in ordinary type :

"A cowboy from Arizona went to San Francisco with his dog, which he left at a dealer's while he purchased a new suit of clothes. Dressed finely, he went to the dog, whistled to him, called him by name and patted him. But the dog would have nothing to do with him in his new hat and coat, but gave a mournful howl. Coaxing was of no effect, so the cowboy went away and donned his old garments, whereupon the dog immediately showed his wild joy on seeing his master as he thought he ought to be."

Any mistakes in reading are noted. If his eyes are not in sufficiently good condition for reading, the story may be slowly read to him. He is then asked to reproduce it in his own words. The result throws some light on attention (IX.), interest, recent memory (VIII.), tendency to invention where details are forgotten (confabulation), emotional responses, and the ability to see the point.

(XI.) **General knowledge of past and recent events.** The grasp of the former is dependent chiefly on education and memory, of the latter (especially those since the onset of illness) largely on the amount of interest which has recently been devoted to ordinary affairs. The patient should be asked to name, for example, the capitals of some of the chief countries of Europe, the dates of the recent war. Knowledge of more recent events is to be estimated from questions based on recent newspaper information.

(XII.) **General Intelligence.** The "average adult" tests of the Binet-Simon scale may be applied in whole or in part, *e.g.* the differences between laziness and idleness, evolution and revolution, poverty and misery, character and reputation, and ability to repeat six digits reversed. Where intellectual defect is suspected, the Binet-Simon series of tests, or a selection from them, should be applied sufficiently to determine the mental age (= total score in Binet-Simon test).

(XIII.) **Insight.** The degree of the patient's appreciation of the fact that he is ill and of ability to regard his symptoms of illness as such is of the greatest importance for prognosis and treatment. The questions already posed under "Mood" and "Thought," and the patient's spontaneous statements, will already have thrown some light on this. In addition, special inquiries should be made, as, for example, "What do you think of your present condition?" "Do you consider your present condition in any way abnormal?" "Is it an illness?" Special incidents should be elucidated, *e.g.* impulsive or peculiar actions, suicidal or homicidal attempts, moral lapses, and anything betraying lack of judgment (*e.g.* monetary extravagance).

Finally, the results of the above investigations should be summarised, the positive findings being tabulated in what appears to be their approximate order of importance for the symptom-picture.

A perusal of the above account of a moderately complete mental examination, together with its application in as many cases as the student can find, will give him some grasp of the spirit and general principles of a psychiatric examination. With this preliminary training, the following brief scheme may be used as a framework for the more rapid clinical examination that the exigencies of time and practice may compel.

ROUTINE EXAMINATION OF MENTAL STATE

(1) *General Behaviour.*

(2) *Stream of Talk.* Note special characteristics, such as slowing, flight of ideas, incoherence. Give brief verbatim sample.

(3) *Mood*.—"How do you feel?" If necessary make the question more specific, e.g. "Sad?" "Afraid?" "Happy?" etc.

(4) *Special Preoccupations*.—"Any trouble recently?" "Peculiar experiences?" "Have you had any imaginations?" "Been fairly treated?" "Persecuted?" "Under any special influence, e.g. hypnotism, electricity, etc.?" *Hallucinations*.—"Do you hear voices?" "Do you see things?" "What, where and when?" *Obsessions and Compulsions*.—"Any troublesome thoughts?" "Have to do certain things in a certain way?"

(5) *Sensorium and Intellectual Resources*. *Orientation* (as to place and date and persons). *Memory* (specially important in organic psychoses). (a) Remote past (life with dates) controlled in taking history. (b) Recent past (some account of past few days). (c) Immediate retention (number, name, objects shown, digits). *Attention*, steady or fluctuating; distractibility. *Grasp of General Information* (kings? premier? wars? etc.). *Calculation*: 100-7 (errors? Time in seconds). *Judgment*.—Ability to make reasonable plans. *Speech and Writing Tests*.

(6) *Insight into Illness*. Any admission of being sick or nervous? Realisation of the nature of the disorder (complete or incomplete).

(7) *Sleep and Dreams*.

(8) Make a special note of topics to be further investigated in subsequent interviews.

THE PSYCHONEUROSES

ANXIETY PSYCHONEUROSIS

This psychoneurosis is a state of mental distress or anxiety, usually accompanied by physical symptoms, which is out of proportion to the apparent facts of the situation in which it arises.

Ætiology. 1. Heredity may play an important part. Some individuals appear to be constitutionally sensitive and therefore prone to emotional over-reaction.

2. Acquired habits of mind as a rule are the chief cause of the illness. These frequently originate in childhood as conditioned reflexes. The emotional reactions of the child depend largely upon those of the adults who surround him. The child whose mother shows signs of terror at a thunderstorm will himself develop an excessive emotional reaction to this stimulus. So with other and more commonplace happenings. If the mother displays anxiety over the child's health, he himself is likely to grow up with an exaggerated fear of illness. Particular emotional experiences also may have a lasting effect in this way. A girl who has been the victim of an indecent assault may develop a morbid fear of the male sex, and so with other kinds of emotional trauma. In adult life the common fault is that of ignorance. In response to some adequate stimulus, an emotional reaction occurs with its train of physical accompaniments. There is, for instance, a feeling of faintness and palpitation of the heart. The subject takes this to be evidence of cardiac disease, and develops anxiety over his symptoms. This in its turn leads to further emotional reaction and palpitation. So a vicious circle is frequently set up which in time becomes a veritable habit. It is doubtful, however, whether anxiety ever develops in this way in a subject not predisposed by temperament, training, or present conflicts.

The original emotional reaction may simply have been misunderstood. Often, however, the emotion itself may have been unconscious, and this for reasons such as have already been discussed. A man may, for instance, be seized with symptoms of excessive anxiety at having to give an account of his work to his superiors. The associated emotion is one of shame and therefore fails to come within the field of consciousness. The emotional reaction, with its consequent palpitation, anorexia, gastric discomfort or other physical symptoms, then

appears as an isolated phenomenon, and actually becomes a source of further anxiety. Unfortunately much harm may result in such cases from erroneous or uncertain medical diagnosis. If the physician accepts the symptoms as having a basis of physical disease, the patient's anxiety is likely to become greater, and the symptoms to be aggravated.

3. Physical disease and disorder may contribute to the development of an anxiety neurosis in two different ways. They may, in the first place, form the starting point for a vicious circle, as has been described, if the patient is already predisposed by past experience to over-anxiety about his health, or if his physician takes an exaggerated view of the gravity of his illness. In the second place, fatigue and toxic illness may by their direct influence upon the mental processes impair judgment and give rise to false perspective, so that molehills in the path of life are regarded with the anxiety due to mountains.

4. The definition given does not exclude environmental stress from the ætiology of anxiety psychoneurosis, but emphasises the apparent lack of circumstantial justification for the patient's reaction. This is because the circumstances mean more to the patient than is consciously apparent either to him or to an observer.

Symptoms. MENTAL. At the root of all the symptoms lies morbid anxiety. This, however, is by no means the most frequent complaint. The anxiety itself may be latent, and the secondary symptoms first lead to a medical consultation. Common complaints are of inability to concentrate, loss of memory, indecision and a general sense of inadequacy. Such are the natural results of continuous anxiety, which fills the mind to the exclusion of other subjects. They are, however, often misinterpreted by the patient, who regards them as signs of approaching insanity. *Insomnia* is frequently an important symptom. Two varieties are met with. In the first, which is associated with manifest anxiety, the patient's mind is so full of his cares as to prevent the onset of sleep. The other is met with where repression has occurred, when the patient is to a great extent unconscious of the emotional origins of his illness. In these cases it often happens at bedtime that the mind becomes over full of a stream of thoughts upon neutral subjects, to the exclusion of any view of the hidden worry, and also of sleep. When sleep has eventually been won in such a case it is often broken by terrifying dreams or nightmares, from which the subject wakes with all the sensations of extreme terror. Anxiety about the sleeplessness and its possible effects aggravates the condition.

The anxiety when manifest may be of a general or of a particular nature. General anxiety reveals itself in a tendency to exaggerate difficulties, and exhibit an excessive emotional reaction to all stimuli. Particular anxieties (sometimes called phobias) are numerous and variable.

Fears of Disease. The patient becomes convinced as the result of some abnormal sensation that he is suffering from a serious disease. The common fears are of cancer, syphilis and pulmonary tuberculosis. Although examination and reassurance may for a time dissipate the fear, it usually recurs until the underlying neurosis has been properly treated. Fears of cardiac, renal and gastro-intestinal disease are also of common occurrence.

Fear of insanity has already been alluded to. It is of common occurrence, and is based by the patient upon the difficulty in mental concentration, and sense of emotional tension from which he suffers.

Fears of certain Situations. These are innumerable. Some of the commonest are fear of open places, of crowds, of closed spaces, of travelling in trains. They may be paralysing in their intensity and seriously interfere with the patient's life.

Fears in relation to Sexual Matters. The commonest of these concerns masturbation. The patient has perhaps practised this habit in the past or continues to practise it at intervals with much emotional conflict. He feels that he has thereby ruined his mental and physical health, and that his illness is due to this cause and

is a punishment for his sins. Any chance encounter with sexual topics gives rise to an emotional over-reaction. The subject being one of which he is ashamed, the origin of his anxiety is frequently, at least for the moment, unconscious. Similar fears may have their origin in anxiety concerning sexual thoughts of which the subject is ashamed. In certain phases of life, and especially in certain persons, these may be of a homosexual nature.

The occurrence of seminal emissions is sometimes the centre of anxiety. Since anxiety itself may result in seminal emission, this is apt to set up a vicious circle.

Impotence in the male is a not uncommon complaint. The symptom may consist of premature ejaculation or of inability to obtain a sustained erection. This is commonly associated with fears concerning past masturbation or seminal emissions.

NERVOUS. *Extreme liability to fatigue* (mental and physical) is a common symptom. The patient complains that he is incapacitated for his work, is unable to sustain his part in conversation, and becomes exhausted after walking up a flight of stairs. Careful inquiry will usually discover that this fatigue is differential in its action, varying with the extent to which the patient is interested in his surroundings. Thus a man may be unable to concentrate upon work of a monotonous character for more than half an hour, yet give his undivided attention to a play for two or three hours at a stretch. Despite his inability to meet the obligations of social small talk, he will discuss at great length and with the utmost keenness the symptoms of his illness, and although he may feel unequal to visiting his doctor, will walk a mile to see a football match without undue fatigue.

Headache is another common symptom. Sometimes it is described as a pain, which is then as a rule intermittent, coinciding with moments of intense anxiety. More frequently it is referred to in terms of discomfort and is continuously present, as a feeling of pressure upon the top or back of the head, a leaden feeling, or a sensation of tightness, fulness or heat.

Giddiness is a frequent complaint. It may be continuous or take the form of attacks which last from a few minutes to several hours. There is no sensation of whirling (as in the vertigo of organic disease), but a subjective feeling of unsteadiness with fear of falling. This fear may be so vivid that the patient dare not move and will cling to others for support. When the symptom is continuous he will sometimes complain that he cannot walk abroad without the arm of a friend to steady him.

Tremor of the limbs is an occasional symptom in association with paroxysm of fear.

ALIMENTARY SYSTEM. Dysphagia is not uncommon. It may be in part due to lack of saliva, but the complaint is usually that the food sticks in the throat and will not go down. It is often associated with fear of cancer. Gastric discomfort and flatulence are common complaints. The feeling is one of fulness which bears no constant relation to the taking of food, but commonly occurs during or immediately after the meal. The patient seeks to relieve this sensation by belching, and in consequence swallows air, which may produce actual distension of the stomach. A characteristic feature of this form of dyspepsia as a rule is its selective nature. The patient will assure us, for instance, that he invariably has indigestion after eating beef but not after mutton; tea is fatal to his stomach, but coffee innocuous; he cannot tolerate green vegetables, but can eat raw apples with impunity.

Constipation is a common complaint. The patient having for some trivial cause been unable to obtain an evacuation and having had recourse to a purge, becomes anxious upon the next occasion whether his bowels will open without the aid of a drug. The anxiety itself interferes with the reflex process of defæcation, and this in turn leads to a habit of mind in which the consciousness of an aperient taken beforehand is necessary to success.

Diarrhœa is sometimes complained of, but on analysis proves a misnomer, the fact being that the patient feels need to open his bowels under particular circumstances, especially when no convenience is available.

CARDIOVASCULAR SYSTEM. Præcordial discomfort and palpitation are the prominent complaints under this head. Extreme liability to blushing may be the focus of anxiety.

RESPIRATORY SYSTEM. Subjective sensations of choking and dyspnœa may occur with paroxysms of panic and fear of impending death.

SKIN. There may be profuse sweating, commonly associated with fears of consumption. Numbness and tingling is an occasional complaint.

Many so-called "neurasthenias" are really anxiety neuroses in which complaints of fatigue are specially prominent.

Diagnosis. This must depend partly upon the exclusion of organic disease as a direct cause of the symptoms, partly upon the recognition of morbid anxiety as their source. As a rule this is not difficult. It must be remembered, however, that certain chronic intoxications, of which phthisis is the chief example, may be important contributory factors.

When the illness has been recognised as a mental disorder it still has to be distinguished from others, such as dementia præcox and manic-depressive insanity.

In some cases of dementia præcox morbid anxieties and fears may occur as early symptoms. These, however, differ from those of the anxiety neurosis in being not only unreasonable, but inexplicable, except in terms of the patients' fantasies if these can be elicited. The patient may, for instance, be anxious about the state of her digestion, but behind this will lie the fixed belief that the lining of her stomach has been corroded away by poisons introduced into her food.

The symptoms of a mild case of manic depressive insanity may resemble in many respects those of an anxiety psychoneurosis. In the former illness, however, depression is usually a more prominent feature, and is largely independent of circumstances. The patient cannot so easily be roused to take an interest in his surroundings; his symptoms show little variation with changes in his environment. He gains little or no comfort from the physician's reassurance, whereas the neurotic almost always shows a marked, if temporary, improvement after such an interview. The manic-depressive is more consistently apt to blame *himself* for his troubles, and will often in giving his story interpose remarks to this effect. His depression also is apt to show a daily rhythm, being at its worst in the early morning. He is less likely to be troubled with difficulty in getting off to sleep than by waking in the small hours of the morning with a feeling of profound melancholy. The differential diagnosis may require in some cases a period of observation. It is important in a doubtful case that it should be settled, for the treatment of the two conditions is dissimilar. There is, moreover, a serious risk in the manic-depressive of suicide.

Prognosis. So far as serious sequelæ are concerned the prognosis is good. These patients do not become insane; but if untreated they may be incapacitated for work and social intercourse for long periods of time, during which they are miserable themselves and a burden to others. With proper treatment the outlook is good except in those cases in which the hereditary factor is prominent.

Treatment. This consists of analysis of symptoms, explanation and reassurance, the procedure being termed psychotherapy. Rest and drugs are also needed in certain cases. Isolation from friends is often desirable at the beginning, and it may be wise to forbid correspondence.

The taking of the history and the physical examination are all-important in the treatment as well as the diagnosis of the condition (11).

The patient should be encouraged to describe his main symptoms in detail, and further questions should then be directed towards the various bodily systems.

Notes should be taken. The patient should then be systematically examined. If analysis of the history and physical examination are sufficient to exclude organic disease, the patient should be told this. If any further investigation is necessary, he should be informed of this, and arrangements should be made as soon as possible for carrying it out. If there are any definite signs of physical disease, this knowledge should not be withheld from the patient, who must be led to feel that he is being treated with absolute frankness. He should further be given some idea of what the signs are and what is their significance. He may thus be led to understand that such organic defects as may be present are insufficient in themselves to explain his symptoms.

The taking of the history and physical examination should occupy at least one hour. Often this is insufficient, and a further interview must be arranged. It is essential that the patient should feel confident that his whole story has been appreciated, and that no possibility of physical disease has been neglected, for these preliminaries form the basis for further treatment.

Having assured the patient that his symptoms are not due to organic disease, the physician should proceed to explain that they are of course real, not imaginary, symptoms, and are such as may have their origin in emotional disturbance. An outline should be given in suitable language of the psychological principles described above (*see* p. 778). It may be pointed out, for instance, that a cat when frightened by a dog shows many disturbances of its bodily organs, including chemical alterations in the blood, acceleration of pulse rate, and rise of blood pressure, which may be measured, and alterations in the gastric movements, which may be observed with the X-rays, yet these changes do not indicate any disease either of the organs affected or of the nerves controlling them.

Further interviews should then be arranged for analysis of the patient's symptoms in the light of these principles.

The symptom is first traced to the date of its origin, and the patient is cross-examined as to any emotional difficulties which may have existed at the time. Often at first he may fail to call to mind any such troubles. The existence of unconscious mental processes should then be explained, and examples given of the way in which an emotional disturbance outside the field of consciousness may nevertheless give rise to symptoms of an emotional reaction.

In this way it is usually possible to discover adequate causes for the various symptoms, and as these are gradually explained they tend to disappear. An attempt should also be made to discover and explain to the patient the underlying habits of mind which have led up to his illness. In some cases these will be plain to his view; in others a great deal of skill and experience may be necessary to unravel the emotional tangle.

Special methods of mental analysis may be necessary in some cases in order to bring to the light unconscious mental processes of importance. For these the works of Freud and his followers upon psychoanalysis should be consulted. The great majority of cases can be successfully treated by less complicated methods. As the patient begins to realise that he is being treated with sympathy and understanding, and that the treatment offers a real hope of recovery, his desire to co-operate gives strength to turn the light of attention towards aspects of his mind which have before been concealed by motives of shame or dread. Thus he gradually reveals himself to the physician, who is able by collecting the scattered threads of the story to discover the causes of his neurosis. In the presentation of these causes the physician needs to be sympathetic, for it will involve asking the patient to face faults and weaknesses in himself to which he has been blind. There is, however, nothing which these people appreciate more than the quiet assurance that others have passed through similar experiences, and that many of their friends (with whom they are apt to compare themselves unfavourably) have almost certainly suffered, perhaps in secret, from the same miseries and fears.

Since the treatment is chiefly concerned with the elicitation and evaluation of symptoms, those which have been described may be considered again under this heading.

An anxiety neurosis, if sufficiently severe and prolonged, is likely to lead to true exhaustion. It is wise therefore whenever symptoms of undue mental or physical fatigability are prominent to commence treatment with a period of rest. Insomnia should always be an indication for rest in bed as a preliminary to further treatment. It is important that the reasons for this procedure should be explained to the patient, who should not be allowed to conclude that rest alone will bring about recovery.

A week in bed, with subsequent return to normal activities in a further two or three weeks, will usually suffice. Psychotherapy should proceed simultaneously. If possible, the patient should be in a nursing home for this part of the treatment.

Mental Symptoms. *Inability to concentrate* is so often interpreted as a symptom of incipient insanity that inquiry should always be made in this direction. The fear is often concealed by the patient from others, if not from himself. This is especially likely if there is any family history of mental disease—a fact sometimes omitted or denied at the first interview. Complete assurance should be given upon this point. It should be made clear to the patient that, although his illness is a mental disorder, it belongs to a class of minor disorders or psychoneuroses which is distinct from the major mental disorders or psychoses, and that patients rarely pass from one illness into the other. The lack of concentrating power should then be explained as being due to anxiety. A man who has some unsettled worry at the back of his mind cannot give his full attention to his work. The origin of the anxiety and the causes of its perpetuation should then be dealt with in the manner already indicated.

Insomnia. In so far as this is directly dependent upon anxiety, it may be expected to improve with treatment of the cause. The patient often develops undue anxiety over this particular symptom, and will then need to be assured that many persons are in the habit of doing good work with fewer hours of sleep than he himself is getting, and that without any untoward symptoms. It should further be explained that anxiety is a *natural* cause of insomnia, and that as the treatment proceeds he will find himself improving in this respect. The power of hidden anxiety to cause terrifying dreams should also be discussed.

If the insomnia is of recent origin, such simple measures are often sufficient. Sleep, however, is a *reflex* process which depends largely upon habit, and this unfortunately holds good also for insomnia. Therefore, if this symptom has persisted for more than a few days, the physician should not hesitate to treat it by means additional to psychotherapy. The patient, as always, should be given an explanation of these means and their rationale.

The additional means available are (1) drugs, (2) habit formation, and (3) muscular relaxation.

1. If the insomnia is of comparatively recent duration, and is an object of much anxiety, the following plan is suitable. The patient is instructed the first night to take a sufficient dose of a reliable hypnotic to induce sleep (medinal grs. x, paraldehyde drs. ii, or chloral hydrate grs. xx, with pot. brom. grs. xl). On the following night he is told to have the medicine ready by his bedside and to take it without hesitation if he finds himself unable to sleep without it. A supply of the hypnotic is prescribed sufficient for a week. The patient should be assured that there is no danger of this procedure leading to a "drug habit." After a few nights it will usually be found that he will fall asleep naturally with the drug untasted by his bed, and will then have regained confidence in his ability to sleep unaided. When the insomnia is of longer duration it may be necessary to give sufficient doses of hypnotics to procure sleep over a longer period, the dose being gradually reduced as psychotherapy and other methods of treat-

ment become more effective. Treatment with drugs should always be combined with the other methods referred to.

2. Most persons have some kind of a ritual which, under normal circumstances, precedes and favours sleep. The hour, the room, the order of undressing, the book read in bed, all play a part as conditions facilitating the sleep reflex. This also is true of insomnia. The patient who is being trained to regain the habit of sleep will therefore benefit from a change of surroundings and of bedtime habits. A change of bedroom is often in itself useful.

3. Muscular relaxation is the most important physical condition for the onset of sleep. Patients suffering from anxiety are frequently in a state of excessive muscular tension, which places them at once at a disadvantage. This symptom, of course, depends upon the underlying neurosis, and improves with treatment of its cause. Nevertheless as a cause of insomnia it may be controlled to some extent by training the patient to relax his limbs. The physician should ask the patient to allow one limb to lie absolutely passive, and test its passivity by raising and handling it. It will usually be found that the patient, so far from letting the limb follow the directions of gravity, is constantly exercising it by his will. With daily practice and concentration, most persons can be taught to relax in turn, and finally simultaneously, all the muscles of neck, trunk and limbs, and this becomes a valuable preliminary to sleep.

Fears of Disease. The preliminary examination must be sufficiently thorough to provide an impregnable position from which the physician can give an assurance that the symptoms are not due to organic disease. This assurance, although it may give temporary relief, is not in itself sufficient treatment. The intelligent patient as a rule will proceed to state that the symptoms exist and must have some cause. The physician then proceeds to explain the manner in which bodily symptoms, often simulating those of organic disease, may result from emotional disturbance. The fear is traced back to the date of its origin, and analysis and explanation are continued. Fears of disease are often associated with primitive ideas of illness as a visitation for past sins, and thus not infrequently have their origin in remorse over sexual misdemeanours.

Fears of special situations should be analysed by giving the patient a preliminary explanation in simple terms of the conditioned reflex and unconscious mental processes. When he has been taught that behind his unreasonable terror there may be an intelligible cause he is urged to carry his thoughts back to the time when the trouble began, and to talk freely of his life at that time, especially of any secret hopes, fears, or disappointments. If the physician himself is sufficiently assured that a cause is to be found, the facts will as a rule gradually disclose themselves. The patient is led to face the truth, and encouraged not to avoid the situations which provoke his fears, but to train himself to meet them in the light of the common-sense explanation which he has received.

Fears in relation to Sexual Matters. The commonest of these concern masturbation. Upon this subject the physician, whatever his own prejudices, must be ready to give unbiassed and impersonal advice.

The patient often feels that in practising this habit he has not only fallen from his own ideals, but has proved himself morally degenerate and unworthy to associate with his fellows. He may be honestly assured that among healthy males there are few, if any, who at one time or another have not practised masturbation, and that the friends and acquaintances with whom he compares himself so unfavourably have certainly had experiences similar to his own.

Additional fears are concerned with the ill effects which masturbation has been supposed to have upon the health. Such notions as that the habit leads to insanity and consumption are occasionally inculcated by ignorant parents or schoolmasters, and are sedulously fostered by quacks for their own mercenary ends.

Actually there is no evidence to show that the act of masturbation *per se* has

any more harmful effects than natural sexual intercourse. The sequels, such as headache and depression, of which the patient complains, are the results, not of the act itself, but of the mental distress with which it is associated, and this is to a large extent proportionate to the patient's fears of its consequences. The patient will often maintain that the seminal loss is in itself weakening. It may be pointed out that it is no greater than in normal sexual intercourse which occurs regularly in the lives of thousands who are in no way the worse for it. As to the remorse occasioned by falling from the standards which he has set himself, it may be pointed out to the patient that possession of such standards is itself a point in his favour, and that it is in the nature of ideals that a man's reach should exceed his grasp.

Fears concerning frequent seminal emissions should be dealt with in similar fashion. Such "losses" cannot cause the symptoms which the patient attributes to them, and are in themselves harmless. Anxiety, on the other hand, may be the cause of seminal emissions.

Frank discussion of these subjects will, as a rule, reduce them to their proper place in the mental perspective and leave the way clear to further inquiry into the origin of the neurosis. The patient who suffers from anxieties of this nature is often shy of confessing to them, but will always respond to inquiries if these are made in the proper way. He should be told that all normal persons suffer to some extent from sex difficulties, and he should be questioned directly about his own experiences in regard to seminal emissions and masturbation.

Difficulties of this nature are less frequently encountered among women, and when present are less easy to disclose. Nevertheless worries over masturbation are not uncommon, and must be discussed with similar frankness if there is reason to suspect their existence.

Sexual impotence in the male is commonly associated with worries over past masturbation. Such a man on his marriage proceeds to intercourse in a state of anxiety lest his past misdemeanours may have rendered him incapable of the sexual act. The anxiety is itself sufficient to cause impotence. When it has been explained to the patient that masturbation is a universal habit he will regain confidence. Or a man who has previously been normal in this respect may attempt intercourse at a time when he is suffering from real exhaustion, and having once failed, may develop anxiety which renders him impotent on future occasions. Here again frank discussion and explanation will often suffice to cure the condition. It is sometimes necessary to see the wife separately and clear her mind upon the subject of sex hygiene. There is no more potent factor in causing impotence than a wife who exhibits doubt or anxiety as to her husband's sexual ability.

Physical Symptoms. After the negative physical examination the patient's symptoms should be examined in detail, and explained as being due to emotional reaction. Such an explanation is often new to the patient, and he may need time to comprehend it. Any attempt at forcing it upon him is likely to arouse opposition. Arguments have to be repeated and illustrations given from other cases or from daily life. Every one knows, for instance, that worry may cause a headache. That a man who stands up to address a large audience may experience a sensation of giddiness or unsteadiness on his feet in association with his anxiety to create a good impression is a matter of common experience. Tremor of the limbs is a frequent accompaniment of fear.

Dyspepsia is a well-known symptom of anxiety. A man whose digestive functions are disturbed by a hidden worry is apt to ascribe his discomfort to some particular article of his food. Having once conceived this idea, whenever he partakes of this foodstuff it is with the fear that it will produce symptoms. The fear itself is sufficient to interfere with normal digestion. A vicious circle is thus set up which is at the bottom of the "selective dyspepsia" which is so common a symptom of the anxiety neurosis. Flatulence is due to misinterpretation of

the sensation of fulness. In his efforts to belch the patient swallows air, and may produce an actual distension of the stomach. If the patient is simply instructed to restrain the impulse to eructate, he may prove for himself the truth of this explanation.

Præcordial discomfort and palpitation are again well-known accompaniments of anxiety, as also are sensations of respiratory embarrassment and perspiration. When the patient is satisfied that his particular symptoms have no organic basis, and are such as *may* be caused by emotion, he is led along the lines already described to call to memory the origin of his symptom and its emotional contexts. Thus the inner history of the illness may in time be disclosed.

The aim of treatment is to give the patient such insight into the origin of his symptoms as will rob these of the appearance of illness. Even when this is accomplished his troubles are not necessarily at an end, for he may still be obliged to meet the emotional difficulties which formed the basis of that illness. Often the illness itself will have provided some excuse for avoiding these difficulties. Recovery may bring with it the necessity to return to distasteful surroundings. Hence at this point there is a tendency to relapse. The patient begins again to doubt his mental or physical fitness for ordinary life. This tendency must be met by analysis and explanation of the unconscious motive which is responsible—the desire to find in illness an excuse for evading unpleasant duties. Often the situation may be made easier for the patient by an interview with relatives or friends, whose sympathy may be enlisted on his behalf.

HYSTERIA

The term hysteria is used to describe a particular variety of mental disorder which finds expression in the form of bodily symptoms, or gives rise to abnormal behaviour of a characteristic type (somnambulism, fugues). Some obviously mental symptoms, however, such as islands of amnesia, or hallucinations, may appear as the total or partial manifestations of a hysterical mental disorder.

Ætiology. Symptoms of hysteria may appear at any age after infancy. They are more commonly met with in the female sex, but under exceptional conditions, such as those met with in the Great War, may be of frequent occurrence amongst adult males. In the majority of cases heredity plays a relatively unimportant part in the ætiology. Of far greater importance are the habits of mind developed by precept and example during childhood and adolescence. In many instances slight physical illnesses or accidents are exaggerated by the parents, who comfort the child with toys or sweetmeats, or the symptoms form an excuse from the performance of some unpleasant duty, or they may secure for the child the desired position of being the centre of attention. In this way too often are laid the foundations of a habit of mind which tends to make the individual unconsciously rely upon physical symptoms as a refuge from the various difficulties of everyday life. On the other hand, the person who is trained in the exercise of his critical faculties, and is able to take a more or less logical view of his life problems, even if he is unable to solve them, is unlikely to develop hysterical symptoms, unless his criticism is disarmed by peculiarly appropriate suggestion. The responsibility of education as an ætiological factor was clearly demonstrated during the Great War, when, although functional nervous disorders were probably equally common among officers and private soldiers, hysterical symptoms were relatively of far more frequent occurrence among the latter.

According to the modern conception of hysteria, the essential point in the ætiology of a particular hysterical manifestation is the presence of an *unconscious motive* for its existence. This has already been illustrated in the instance quoted above of the soldier developing a hysterical paralysis under stress of warfare when the unconscious motive was the desire to escape from danger. In other cases, the motive may be much more difficult to understand, but it is probable that in all cases it exists. Thus fits of a hysterical nature

occurring in a young woman may be shown to result from a repressed wish to attract to her side an inattentive lover, a paralysis or tremor of the right hand may occur under circumstances which demand the writing of an unpleasant letter, or the symptoms may have as their motive in a shy individual the desire to assert himself and to become the centre of attention.

An additional cause for the symptoms is usually to be found in the shape of a *suggestion*. This may come from within. For instance, a woman has a twinge of pain in the back; she remembers a friend who had the same symptom and afterwards developed paralysis of the legs, and is convinced that she is suffering from a similar disease. Or the suggestion may come from without, from the chance remarks of friends or the erroneous opinion of a medical man.

Whatever the suggestion of disease, it is accepted without logical grounds by reason of the unconscious motive in the background. There is no more satisfactory excuse for evading emotional problems than the assumption of illness. This, of course, is well recognised by the malingerer. But there is a real difference between the malingerer and the patient who is suffering from hysterical symptoms. The business of the former is to deceive others; the patient with hysteria deceives himself, and to provide a satisfactory solution of his difficulties this self-deception must be complete. The malingerer can, and will, discard his symptoms whenever it may be convenient; the hysterical disability, however inconvenient it may be in some ways, remains constantly present until the patient's belief in its reality is removed.

The **Symptoms** of hysteria may be of the most diverse nature, and may closely simulate many forms of organic disease, from which they are to be distinguished only by careful examination. By certain writers in the past a good deal of stress has been laid upon the value of certain physical signs said to be pathognomonic of the condition and therefore known as the *stigmata* of hysteria. More recently, however, it has been shown that these signs have probably in all cases been due to suggestions made by the physician in the course of physical examination. It is to be remembered that the hysterical patient is lacking in the critical faculty, and therefore his judgments upon the nature of his own bodily sensations are likely to be influenced by the least suggestion made by another, especially if this falls in with his own fixed idea of serious physical illness and is made by a person in whose knowledge of disease he has implicit belief. Therefore, for instance, in the course of our examination of cutaneous sensibility, the tone in which an inquiry is addressed to the patient may suffice to determine his answer, even if this be at variance with all considerations of common sense. Thus may be developed areas of cutaneous analgesia in which the patient states that he is unable to feel the pricking of a pin, even if this is pressed in deeply enough to draw blood. Or in the examination of the visual fields abnormalities may be discovered which vary with, and depend upon, the method of examination (Hurst).

It is important to remember that in a large number of cases of hysteria there are to be found signs of underlying organic disease either of the nervous or other bodily systems, which has formed the starting point for the development of a neurosis. The physician must, therefore, be prepared on occasions to find signs of hysteria and of organic disease in the same patient, and must, in summing up the case, decide what proportion of the symptoms is functional and is, therefore, amenable to cure by psychotherapy. For instance, a patient may be seen complaining of paralysis of the whole arm from the shoulder downwards starting from an injury received at work; examination reveals the scar of the injury to be below the elbow; the signs of division of the ulnar nerve at this level are present in the form of the appropriate wasting of the small muscles of the hand; sensory examination, however, shows the anæsthesia to extend up to the level of the axilla, and there is total loss of power of the muscles without any wasting or alteration in the tendon jerks. In such a case the greater part of the symptoms

may be removed by the methods of psychotherapy to be described later, leaving a small organic residue which needs surgical treatment. Or a woman may be seen who has for some months been bedridden with total paralysis of the legs. Examination of the nervous system reveals definite signs of organic disease in the form of extensor plantar responses and absent abdominal reflexes, and a careful analysis of the history is sufficient for the diagnosis of disseminated sclerosis. Yet the defects of nervous function in the shape of paralysis, loss of sensibility, spasticity, or inco-ordination, are insufficient to account for the inability to walk. In such a case psychotherapeutic measures, though, of course, without any effect upon the underlying organic disease, may serve to restore to the patient the power of walking. Some of the commoner manifestations of hysteria will now be described under the headings Mental, Nervous and Visceral.

Mental Condition in Hysteria. It has already been stated in the definition of hysteria that the disorder is primarily one of the mental processes, and although the outward manifestations of this disorder usually take the form of physical symptoms, the mental condition may sometimes be recognised in the general behaviour of the individual. The essential feature in the mental state of hysteria is the process of dissociation whereby a group, or complex, of ideas and feelings belonging to the personality is shut out from the field of consciousness. In certain cases there may occur temporarily a complete reversal of this state, so that the whole field of consciousness is filled for the time being by the ideas and feelings previously excluded, while those which formerly constituted the conscious mental activities of the individual are, in their turn, shut off. Thus arise the cases of dual personality in which a person may for a period of minutes, hours, or even days, speak and behave in a manner wholly foreign to her usual demeanour, and on returning to her usual self have no memory whatever of what has occurred. In its simplest form such dissociated behaviour takes the shape of sleep walking, of which the classical example in literature is that of Lady Macbeth in Shakespeare's play. Waking episodes of a similar but usually more complex nature are called "hysterical fugues." The same mental process of dissociation is responsible for the condition of so-called hysterical amnesia, in which the individual loses all memory of some phase of his life which is associated with painful and unpleasant experiences.

The patient with physical symptoms of hysterical origin does not, as a rule, show signs of emotional stress, and is, therefore, not commonly "hysterical" in the lay sense of the term. On the other hand, it is frequently to be observed that these patients, in spite of a superficial anxiety to be relieved of their symptoms, show no real depth of feeling in this respect, and are, in fact, abnormally content with their condition. This is easily understood if it be admitted that the symptom itself is providing satisfaction for certain underlying wishes in the patient's mind of which he himself is not clearly aware.

Nervous Symptoms. *The Hysterical Fit.* The attacks known as hysterical convulsions and "fits of hysteria" are commonly caused by emotional disturbance. They occur as a rule in the presence of others, or in circumstances where they are likely to attract attention. The patient may complain of sensations of choking, giddiness, or faintness, and burst into a fit of crying or uncontrollable laughter. In other cases the patient falls to the ground, as a rule gently, or on to a chair or sofa, and at once passes into a state of convulsive movements. These, if they are witnessed by the physician, are as a rule easily discerned to be of a purposeful nature. There may be phases of tonic contraction in which body and limbs are held stiffly with hands clenched, but these never involve the respiratory muscles to such a degree as to produce cyanosis. The eyelids are generally closed, and resist attempts to open them; if they are opened, the eyeballs are rolled upwards under the upper lid. There are no true clonic twitchings. The patient may tear at her clothes, beat her head with her hands, or clutch at bystanders. She may gnash her teeth, and saliva may issue from the mouth, but the tongue

is not bitten. There is no loss of sphincter control. Often the attack is punctuated by shrieks, groans or articulate cries. There is no true loss of consciousness. Though the patient does not reply to questions, she is influenced by what is said or done in her presence. The greater the alarm evinced by those around her, the more violent is the display of excitement. The attack may continue in this way for two or three hours. If the patient be ignored, the symptoms may at first increase in severity, but if treated quietly, rapidly diminish. Neither during nor after the attack is there any disturbance of the reflexes. At its conclusion recovery is as a rule rapid, and the patient is in a few moments again in possession of all her faculties. All knowledge of the episode may be denied. This is often a pretence, but may be due to a hysterical amnesia, in which case the patient becomes able as the result of treatment to recall the incidents of the attack.

Disorders of the Special Senses. Hysterical blindness is by no means common; but many cases have been recorded arising out of the Great War. In most instances they occurred in the case of a man exposed to irritating gas and for the time being unable to see on account of acute conjunctivitis, photophobia and blepharospasm. Some of these patients remained blind for years before their symptoms were removed by psychotherapy. In such cases, of course, there are no abnormalities to be found on ophthalmoscopic examination. *Hysterical deafness* is not infrequent, and was another symptom commonly observed during the war in a man who had been temporarily deafened by the explosion of a shell. It is usually unilateral, but may affect both sides. Hysterical deafness may be diagnosed by the absence of any history or signs pointing to chronic inflammation of the middle ear, and by the performance of the tests for vestibular function. If under such circumstances the reactions to these tests are normal, the deafness is almost certainly of hysterical origin.

The Cranial Nerves. Hysterical spasm of the orbicularis palpebrarum, or blepharospasm, is of quite common occurrence, and usually accompanies hysterical blindness. It commonly follows irritation of the conjunctivæ, as in chronic conjunctivitis, the usual cause in the war being irritant gas. The face and tongue also are sometimes affected by spasm. In this way a hysterical patient may simulate facial paralysis by contraction of one side of the face, the other side appearing weak by contrast while at rest.

Hysterical mutism is a not uncommon symptom, and has already been referred to. It may appear after a severe emotional shock, as, for instance, in the war cases, in which it may be imagined that the individual was for the moment struck *dumb with terror*. The patient is unable to make any sound whatever on attempting to speak, yet in some cases he may be able to cough quite audibly. In the condition of *hysterical aphonia* the patient is able to speak only in a whisper. This most commonly arises after an attack of catarrhal laryngitis, and may be regarded as a perpetuation of a symptom which was originally organic. On laryngoscopic examination the adductors of the vocal cords can be seen to be immobile. It is noteworthy that in a number of these cases the patient speaks in a high-pitched whisper without any hoarseness, which is in itself a point of diagnostic value. (See Paralysis of Laryngeal Muscles.)

Sensory Symptoms. Complaints of pain or tenderness not infrequently occur as accompaniments of local symptoms of a hysterical nature. Thus there may be complaint of headache or backache and tenderness over the top of the head or the vertebral spines, or in association with hysterical contractures of the limbs there may be complaint of great pain on attempted movement. Hysterical anæsthesia has already been referred to, when it was stated that this symptom is usually produced as the result of neurological examination. It is often present also as an accompaniment of hysterical paralysis. It may usually be distinguished by the nature of its distribution, which does not follow any anatomical laws, but depends on the patient's own idea of anatomy. Thus,

accompanying a paralysis of hand or foot, it is usually of a "glove" or "stocking" distribution.

Motor Symptoms. These may be divided into paralyses and contractures and involuntary movements.

Motor paralysis is one of the commonest of all hysterical symptoms. It may take the form of a monoplegia, a hemiplegia, paraplegia of the legs, or paralysis of all four limbs. The paralysis is usually complete and may be flaccid, or accompanied by contracture of the muscles, the latter form being the commoner. As a rule, it is of sudden onset, commonly following physical or emotional trauma, or it may often appear in the form of a perpetuation of a weakness of organic origin, as, for instance, after a fracture for which the limb has been splinted for a considerable time. In both the flaccid form and that associated with contracture, the paralysis usually affects all groups of muscles equally without regard to cortical, segmental or peripheral nerve distribution. When the patient is requested to put the paralysed limb into action, in spite of much exhibition of effort, there is little or no movement. It is to be noted that, although there may be some atrophy of the muscles from disuse, this is never so marked as in the case of a lower motor neuron lesion, and that in the cases with contracture the rigidity does not conform either in type or muscular distribution to the clinical picture of spasticity from a lesion of the upper motor neuron. Moreover, the anæsthesia which is frequently present follows no anatomical laws in its distribution, nor is there any abnormality of the tendon jerks. One phenomenon of positive value in the diagnosis of hysterical paralysis is the simultaneous or rapidly alternating contraction of the prime movers and their antagonists in attempting to perform any particular movement. Thus, if the patient with a hysterically paralysed arm be asked to perform the movement of flexion at the elbow, the observer by simultaneous palpation of both biceps and triceps can feel these muscles contracting simultaneously, or in rapid succession, so that, in spite of much expenditure of muscular effort, either no movement at all or else a succession of jerks occurs. This phenomenon does not occur in any condition due to organic disease. In some cases a hysterical contracture may closely simulate an organic condition, but may usually be differentiated by careful neurological examination. In contrast with the rigidity of organic nervous disease, it will be found in hysteria that the force opposed to passive movement varies directly with that applied by the observer. A form of paralysis of quite frequent occurrence in hysteria has been described as *astasia-abasia*. In this condition the patient is able to perform all voluntary movements of the lower limbs with normal power and accuracy so long as she is lying in bed, but is unable to walk when set upon her legs. The involuntary movements of hysteria may assume the most diverse forms, of which various types of tremor may sometimes with difficulty be distinguished from those of organic disease. The signs, however, which are usually associated with the organic tremors of Graves' disease, disseminated sclerosis, paralysis agitans and other diseases are absent.

The reflexes in hysteria do not as a rule show any abnormalities, though it has been stated (Hurst) that in cases of hysterical anæsthesia of the abdomen the abdominal reflexes may be absent, to return with the disappearance of the anæsthesia.

The functions of micturition and defæcation are sometimes affected; the commonest symptoms being retention of urine on the one hand and dyschezia on the other. In such cases, great care must be taken to exclude the possibility of organic disease.

Abnormalities of the posture and gait in hysteria are as a rule easily distinguished from those which depend upon organic lesions. Disorders of gait in some instances take the form of mannerisms, such as hopping or prancing, or even of walking sideways crab fashion. Among the postural abnormalities may be

mentioned that of the bent back simulating that seen in some advanced cases of osteoarthritis of the spine.

Trophic changes do not occur as isolated symptoms in hysteria. Although blueness of the skin and brittleness of the nails may be seen in long-standing paralysis of hand or foot, these are but the concomitants of disuse. In some cases of contracture of prolonged duration, excoriation of the skin may occur in the neighbourhood of the joints.

Hysterical dysphagia is not uncommon, and may be associated with the sensation of *globus hystericus*. There is no reason for supposing that this particular sensation is different in its physiology from the "globus" sensation which normal people experience from time to time, and which is produced in the œsophagus (see p. 333).

So-called *hysterical vomiting* and *aerophagy* have been mentioned under the Tics and are described on pp. 338 and 341.

Hysterical polypnœa is a condition in which there is extreme rapidity of respiration unassociated with any pulmonary disease. Although the rate may amount to sixty or seventy respirations a minute, the individual breaths are very shallow.

Diagnosis. This depends, in the first place, upon the exclusion of signs of organic disease sufficient to account for the symptoms observed. There are, however, some symptoms which are in themselves of positive value in making the diagnosis, such as aphonia with isolated paralysis of the adductors of the vocal cords, and the simultaneous movement of prime movers and antagonists in a paralysed limb or muscle.

The association of paralyses which could not be accounted for on the basis of a single lesion is also a suspicious circumstance, such, for instance, as an inability to open one eye together with an apparent paralysis of the same side of the face. The failure of a muscle to function in one movement, together with good power in the performance of another, may also be a valuable point in evidence. The circumstances under which the illness has arisen and the previous history of the patient, with special reference to her reaction to emotional difficulties, may also be useful; but the mere fact of the symptoms having immediately followed an emotional shock is not to be taken as evidence of their hysterical nature, since a cerebral hæmorrhage or an attack of genuine epilepsy may be precipitated by such conditions.

Of organic nervous diseases, that most likely to be confused with hysteria is disseminated sclerosis, but the mistake made is usually that of diagnosing the organic condition as functional.

In difficult cases, especially those in which a hysterical disability is superimposed upon an organic affection, it may be necessary to resort to psychotherapy as the final criterion. Symptoms which are removed by these methods must be of mental origin.

Diagnosis of a Hysterical Fit. The features described above (p. 788) serve to distinguish this from an epileptic fit if the physician is able to witness an attack. Often, however, the diagnosis has to be made upon the history alone. Here points which are definitely in favour of epilepsy are the occurrence of attacks when the patient is alone, especially if he falls and hurts himself, true disturbance of consciousness, cyanosis, biting of the tongue, incontinence of urine, and a period following the attack in which the patient is dazed or behaves in an automatic manner. The epileptic often gives a groan at the commencement of the fit, but is thereafter silent; the hysteric frequently continues to cry out during the whole attack. The duration of the movements in an epileptic attack is brief—as a rule not more than ten minutes; in the hysterical fit they are commonly of longer duration. The circumstances of onset have also to be considered. It must be borne in mind that an epileptic may also have hysterical fits, and that after an attack of minor epilepsy the patient may sometimes pass into a hysterical condition.

The **Prognosis** in hysteria is on the whole good as far as individual symp-

toms are concerned, although this depends to some extent upon early diagnosis and proper treatment. A person with hysterical paraplegia, if the condition be pronounced a grave one by the physician, may remain bedridden for years, yet even so she may recover spontaneously, the symptoms disappearing suddenly and being attributed in most cases to emotional shock. Of such a nature are the many "miraculous cures" effected by quacks. On the whole, it may be said that the longer a symptom has persisted the more difficult it is to remove; when the symptoms are of short duration they are easily caused to disappear. The underlying disorder of the mental processes, however, is by no means so easily remedied, and it is a notorious fact, therefore, that the hysterical patient is liable to relapses in which the original symptoms may be reproduced or new varieties may be displayed. In estimating the prognosis, due weight must be given to considerations of the patient's power of intellectual grasp and the environmental circumstances against which she has to contend.

Treatment. Hysteria is a disorder of the mental processes, and treatment must therefore be directed towards the mind, the general title given to the methods employed being *psychotherapy*. The forms in which psychotherapy may be used in the treatment of hysteria are classified as *suggestion*, *persuasion* and *analysis*.

An outline will be given of these three methods, together with some indications for the use of each, but it will first be of value briefly to restate the theory already enunciated of the causation of hysteria.

The condition, then, is one in which the patient is led by motives of which he is unconscious to accept the suggestion that he is suffering from bodily illness. The relative importance of these two causes, unconscious motive and suggestion, varies in different cases. When the unconscious motive is powerful, as in the case of a workman seeking compensation, the suggestion may be of trivial importance. On the other hand, a definite diagnosis of organic disease made by a medical man of standing may need no more support than a natural tendency to surrender to illness in order to produce a hysterical symptom.

Whatever the chain of mental processes which has led up to the hysterical condition, the penultimate link is the patient's conviction that his symptoms exist and are dependent upon physical causes over which he has no control. It is the aim of psychotherapy to remove this conviction, and this may be accomplished by any one of the methods already mentioned or by the use of all three in combination.

The object of all three methods is to replace the patient's conviction as to his symptoms by another and opposite belief.

The method of *suggestion* aims at achieving this end by making use of emotional or instinctive trends in the patient's mind, of which the most important are his implicit belief in the knowledge and power of the physician and his readiness to expect miraculous cures from treatment which is novel, spectacular, or mysterious. The success of this method clearly depends to a large extent upon the personality and reputation of the physician, as also upon the readiness of the patient to abandon the exercise of his critical faculties.

The technique of the method may be illustrated as follows: The physician is asked to see a woman with a paralysis of the arm. Having discovered that the paralysis is functional, he will remark to the patient that the condition is a nervous one, which is readily curable by means of a new form of electrical treatment; he will mention the fact calmly with the air of one accustomed to such cases and their cure, and may proceed to relate one or two instances which have occurred in his practice in which long-standing paralysis of this type has been completely removed by a single application of the new treatment. Having led the patient's friends and relations also to expect an immediate and certain cure, he will return later with a faradic battery and wire brush, and after further preparation of the patient's mind will apply the current to stimulate the muscle groups of the affected limb, at the same time insisting that she has recovered her powers of

voluntary movement. Similar methods may be applied to the treatment of other hysterical symptoms. The actual instrument used is of no importance, provided that the method is new to the patient. If, for instance, faradism has previously been tried and has failed, some new means must be devised. The essential fact in successful treatment is the establishment of implicit confidence of patient in physician. It will be noticed that when this method is employed the conviction of cure by which the conviction of illness in the patient's mind is replaced rests not upon any reasoned chain of belief, but upon instinctive feeling.

Hypnosis may be regarded as a form of suggestion, which has been now largely abandoned in favour of more direct methods in the treatment of hysteria.

The object of *persuasion* is to induce the patient to replace the false conviction as to his illness by a reasoned belief. To take the instance of functional paralysis of the arm again, the physician will explain to the patient that there are no signs of disease of the muscles of the limb, or of the nerves controlling it; that a muscle which can be used for one movement must be equally available for another, and therefore that if she first relaxes the muscles of the affected limb, and then sets out with the single aim of performing a definite movement, she will be able to accomplish it. The advantage of this method over suggestion is that it leaves the patient with a conviction of cure which is more stable in that it depends upon a chain of reasoned arguments which she can reproduce for herself in time of need. The disadvantages are that it makes a certain demand upon the intellectual, and especially the critical, faculties of the patient, and that it takes longer, and is perhaps for this reason less certain in its immediate effects.

In practice these two methods of suggestion and persuasion are usually combined, for it is clear that the success of the latter method must depend upon the implicit confidence of the patient in her physician as well as upon processes of cold reasoning.

The method of treatment by *analysis* has a much deeper purpose, namely, to discover the whole chain of mental processes leading up to the production of the hysterical symptoms, and to remove these by helping the patient to readjust his mental attitude in the light of the analysis. If the patient can be led to an insight into his own condition, and is enabled by the methods of analysis to recall to consciousness the dissociated ideas which are the basis of the hysterical symptoms, the latter tend to disappear as the ideas and the feelings associated with them are assimilated. Such a procedure involves more or less complete self-understanding on the patient's part, and protects him much more effectively against relapse than the other methods.

Analysis of this kind may be a comparatively simple matter, or it may call for much patience and skill on the part of the physician, and the use of certain technical methods (*see* p. 781). To take as a hypothetical instance again the case of a young woman with functional paralysis of the arm, the physician may discover that, having hitherto lived at home, she has lately for the first time in her life been away in domestic service, that she has found her new duties trying, has been feeling very homesick, and has not obtained the sympathy she desired either from her co-workers or her parents; further analysis of the patient's inner thoughts and feelings, as well as of her behaviour and utterances, leads to the conclusion that the unconscious motive for her illness has been the desire to escape from her unpleasant duties and to gain sympathy from those around her, the precipitating factor having been a trivial injury sustained at work. The patient is given this explanation of her malady and is encouraged to meet her emotional difficulties frankly, being told that when she does so her symptoms will disappear. It is clear that he who employs this method is at the same time availing himself of both suggestion and persuasion, which probably play a considerable part in the procedure, since appeal is made both to the patient's implicit belief in the physician and to her powers of reasoning about her own mental processes.

In the practical treatment of hysteria these three methods of suggestion, persuasion and analysis are generally used in combination, due consideration being given in every instance to the intellectual grasp of the individual, and to the time available for treatment, in deciding which shall be chiefly relied upon. There are some patients of low educational level for whom crude methods of suggestion alone are the best available. In all other cases it is advisable as a preliminary step to give the patient some kind of explanation of his illness in terms which will help him to understand the nature of the disorder and the rationale of the treatment to be adopted. After this it is well to begin with the removal or alleviation of the symptoms by means of suggestion and persuasion, which may be followed up by analysis in selected cases. Whenever possible the patient should be led to realise that his illness results from a disturbance of the mental processes—processes which he can, if he will, examine and control. Since the perpetuation of hysterical symptoms frequently depends upon the patient's emotional reactions to factors in his environment, it is of value in many cases to have him removed to a nursing home or hospital before treatment is commenced, and to forbid him receiving letters or visitors until the cure is complete.

In conjunction with mental treatment carried out on these lines, the physical condition of the patient should be carefully considered, and every effort made to eliminate physical causes of bodily inefficiency, whether in the nature of septic foci or faulty habits of life.

AFFECTIVE REACTION TYPES

THE MANIC-DEPRESSIVE PSYCHOSES

The characteristic feature is the predominance of affective (emotional) abnormality in the direction of excess of happiness (elation) or of excessive sadness (depression). This is accompanied by a corresponding disturbance of thought and action, and the correspondence is characteristically a harmonious one, the elated patient being also over-active (psychomotor over-activity) both in the more physical sense of incessant busy-ness and in the domains of thinking and speech, as shown by the continuous talkativeness; while the depressed patient, on the other hand, shows a corresponding reduction of activity, sitting doing nothing for hours at a time. Besides being reduced in quantity, his activity both of thought and action is slowed (psychomotor retardation). These are the leading characteristics of the typical forms of the manic-depressive psychosis; but there are intermediate and atypical forms, which will be described below (8).

Incidence. Patients suffering from this form of psychosis constitute 16 per cent. of the admissions to mental hospitals; but many more with a mild degree of the condition do not become resident in hospital.

Ætiology. There are some facts and many theories. Inheritance is undoubtedly a frequent factor. Eighty per cent. of patients show a morbid taint of some kind in recent ancestors or collaterals, but this figure covers such a heterogeneous diversity of conditions as organic brain disease and vagrancy. More important is the evidence that a direct similar inheritance from parent to child is relatively common. If one parent has had a psychosis of this type, it is said that one-third of the children will also have it, while others will exhibit a cyclothymic personality.

Constitution, mental or physical, is a predisposing factor. The temperament more prone than others to develop a manic-depressive psychosis has been variously called "syntonic," "cycloid" or "cyclothymic." The characteristics are persistent cheerfulness or quiet sadness, with a tendency to fluctuate from one to the other, and an open, frank, sociable attitude. The depressive type of cyclothymic personality was found in 64 per cent. of a series. The principal depressive traits in the series were worry, periods of gloom and lack of confi-

dence. The elated or hypomanic type of cycloid personality is always very active and cheerful, full of affairs and sociable to a high degree. A manic-depressive psychosis is held to be more commonly found than other types of psychosis among persons of "pyknic" constitution, although its occurrence is not by any means confined to persons of this physical make-up. The "pyknic" physique is of middle height, muscular, given to *embonpoint*, with a short neck and rounded head and face.

Women are more commonly affected than men (70 : 30), and Jews relatively more frequently than Gentiles. Fifty per cent. of all first attacks occur before the age of thirty. A case has been recorded as early as five years of age; but the period fifteen to thirty years of age is the one of greatest susceptibility. A change in type occurs as age progresses, depressions, which are always the more common form, becoming even more frequent in proportion to instances of manic excitement.

Precipitating Causes. Stress, mental or physical, can usually be found preceding the first attack; any physical illness may precipitate an attack in a predisposed person. This has to be distinguished from the liability of manic-depressive patients to develop intercurrent infections as the result of their carelessness of themselves. Mental stresses are more frequently found than serious physical ones. Bereavement, financial loss, domestic difficulty, disappointment of any kind, frustrated love-affairs, and the like, are all frequent precipitants of first attacks. Subsequent attacks occur with much less, or even no, apparent external provocation.

Theories. (a) Physical. A disordered metabolism, an organic basis of, *e.g.* structural brain-disease, and a toxic origin have all been invoked, on insufficient evidence so far. (b) Psychological. A special, often inherited, affective constitution has been suggested to account for the persistent emotional disturbance so characteristic of manic-depressive psychoses, this constitutional tendency being released in the circumstances noted. Psychoanalysis has postulated, in addition to a constitutional factor, an arrest (or *fixation*) of the development of the libido at the anal or sadistic level.

Psychopathology. Manic elation can be regarded as the emotional accompaniment of a phantasy, which pleases the patient and in which he becomes exclusively interested at the expense of reality. Depression, on the other hand, may be simply the exaggeration, perhaps on a constitutional basis, of the downheartedness that normally accompanies disappointment; or it may be the conscious accompaniment of a feeling of guilt and wrong-doing, the origin of which remains repressed and unconscious. When the basis of elation or depression remains unconscious in this way the emotional disturbance naturally appears inexplicable both to the patient and the observer (9).

Mental Symptoms. These are usually described in triads, of elation, motor activity, and flight of ideas, on the one hand (manic phase); and depression, diminution of activity, and slowness of thought (retardation), constituting the depressive phase, on the other. In addition, there are mixed conditions in which symptoms are combined in various ways, *e.g.* elation plus immobility plus poverty of ideas constitutes "manic stupor."

Manic Phase. Three degrees of intensity are described: hypomania, acute mania, and acute delirious mania, in that order of increasing severity. The onset in all is usually sudden.

(1) The hypomanic patient is always busy, sleeps little, rises early, drives his car at breakneck speed, talks much and loudly, writes numerous letters (psychomotor excitement), begins many things and finishes none (distractibility). He is very happy (elation), laughs, jokes, and puns. His talk shows a rapid change from one topic to another, the change occurring often on the basis of superficial associations (flight of ideas). "Clang" associations, depending on the similar sounds of words, are a common type. The mood shows sometimes a rapid but

temporary change to irritability. Inhibition is diminished—the patient says things not heard in polite society, is rudely outspoken, and may drink to excess or indulge in venery. The intellectual and sensorial functions (memory, etc.) are well preserved. Insight is lacking.

(2) Acute Mania is a further development of the above condition. The classical triad of symptoms is again present; but the over-activity has reached a pitch of incessant restlessness, of an increasingly aimless character. Sleep is reduced to a minimum, food is neglected, and talk is incessant. The change of conversational topic may be so rapid as to produce the impression of incoherence. Attention is so distractible (the patient commenting on any chance noise or incident in the midst of his activity) that recent memory and orientation are interfered with—he notices nothing long enough to remember it. The patient's gaiety is infectious, but changes readily to irascibility, which may, in combination with the over-activity, lead to acts of violence. Destructiveness in the form of tearing up bedclothes and destroying articles of furniture is common. Clothing is divested, so that often a special indestructible one-piece suit is necessary to keep the patient from exposing himself to cold. Delusions are frequent, ordinarily grandiose, sometimes persecutory, but usually transient and loosely organised.

(3) Acute Delirious Mania. Clouding of consciousness is the prominent feature of this stage. Complete disorientation in all spheres accompanies the extreme restlessness. Attention is very fleeting, and misidentifications and hallucinations are prominent. The patient sees visions and hears voices, all in a transitory disconnected way. The mood, typically elated, changes rapidly to ecstasy or despair, and back again. The activity includes dancing wildly, shouting and screaming, throwing things about, smearing the walls and furniture, tearing up clothes, etc. Talk is incessant and consists of prayer, abuse, entreaty, punning, rhyming, and the like. The patient seems tireless, but in reality is wearing himself out and succumbs readily to infections. It is in fact probable that most, if not all, cases of acute mania of delirious intensity are associated with infection, which has much to do with the intensity of the symptoms.

Depression. (1) Simple retardation consists of sadness with reduction of activity both in speech and action (psychomotor inhibition). There is a slowing (retardation) as well as reduction. The slowing is both initial (slowness in beginning an action) and executive (slowness in carrying it out). In thinking and speech the retardation is more marked in relation to special topics ("Painful thoughts are slow"). The patient complains of difficulty in thinking. The mood is one of hopelessness, and there is a lack of emotional resonance; nothing has any joy or interest in it. The content of thought exhibits ideas of unworthiness, of actual sinfulness and of failure. Obsessive fears, especially of harming those dearest to the patient, and obsessive thoughts of a sacrilegious nature, are common. A desire for death and suicidal intentions are universal at one stage or another, although the retardation fortunately puts an obstacle in the way of their execution. The world and the patient himself seem to him strange and altered (feeling of unreality). Intellectual and sensorial functions are intact, except that mental operations, as a whole, are slower. The patient looks distressed or anxious, and sometimes complains that he cannot weep. He sits almost immobile for hours at a time, head bowed, and hands on knees.

(2) Acute Depression. This is a further stage, with even more obvious inhibition and retardation. The patient says nothing spontaneously and moves little. Questions are answered monosyllabically. The facies and posture make a picture of gloom. Delusions of economic, bodily and spiritual ruin persist, in spite of all persuasion to the contrary. The patient believes he has ruined himself by masturbation or other misdeeds; that he is faced with financial disaster and that he has ruined his family (delusion of poverty). Hypochondriacal delusions reach a considerable pitch of exaggeration: the bowels are stopped up, the brain

is disintegrating, and the entrails are rotten. These may be based partly on alteration of physiological functions (*v. infra*). Food is refused, usually because the patient believes he is unworthy. Much more rarely he believes the food is poisoned, but delusions of persecution of this kind are not typical. Sensorial and intellectual functions are intact, but there is no insight.

(3) In Depressive Stupor the patient is so completely absorbed in his hypochondriacal and self-accusatory delusions that he takes no interest in his environment whatsoever. No question is answered. He has to be tube-fed ; he does not attend to the calls of nature, and retention of urine and fæces results. It is impossible to test the intellectual and sensorial functions, but, naturally, knowledge of current events is interfered with on account of the lack of interest.

“ *Mixed* ” States. These are principally as follows : Agitated depression—depression of mood plus bodily over-activity (restlessness, wringing of hands, bemoaning of fate), but still with retardation in thinking. Manic stupor—elation plus complete inactivity and indifference to environment. The patient is preoccupied with fantastic delusions of his happiness and importance. These are the only two “ mixed ” states met with at all commonly. Manic stupor is probably always a transition stage between depression and mania or the reverse. Unproductive mania (elation with poverty of thought), depression with flight of ideas ; akinetic mania (elation with flight of ideas but lack of motor activity) ; anxious mania (anxiety, psychomotor activity and flight of ideas), are all very uncommon. The importance of recognising mixed states lies chiefly in the more prolonged course of the illness in which they occur.

Physical Symptoms. Sleep is much reduced and difficult to control with remedial measures. Loss of appetite and refusal of food lead to emaciation in depressed patients ; over-activity and carelessness about food lead to the same result in manic patients except in hypomanic cases, who may slightly increase in weight. There is a diminution in all secretions in the depressive phase, with which constipation is correlated. The skin becomes dry and harsh and the growth of the nails irregular. The opposite conditions obtain in manic excitement. Metabolism, as measured by gas-exchange, urinary secretion, blood-pressure, and the like, show no characteristic alteration. Menstruation, as in all mental illnesses, is frequently disturbed. Not infrequently an improvement in these physical symptoms precedes the beginning of a recovery from the psychosis. Fragmentary indications of hyperthyroidism appear in some manic patients. Some depressed patients show a delayed fall in the sugar tolerance curve.

Course and Prognosis. Recovery from the individual attacks, and recurrence are the principal features. A second attack occurs in at least half the cases. Some patients have a recurrence nearly every year. Nearly 50 per cent. of cases show depressive attacks only, and 16 per cent. manic attacks only ; the remainder show both at some time or another. Manic and depressive attacks may succeed one another immediately (circular insanity) or after an interval (alternating insanity). Depressive attacks may succeed each other, and so may manic attacks (recurrent depression, recurrent mania). The duration of an attack ranges from four or five days to many years. Recovery can occur even after fourteen years. The interval between attacks has been as long as forty-four years. With recurrence the free intervals tend to become shorter and the individual attacks longer, until sometimes the illness becomes continuous. When attacks have been often repeated, a terminal state of mental enfeeblement is apt to occur—a state of mild depression with little interest and little activity. A few patients remain in a state of chronic mania, especially those past middle age. These patients are over-active busybodies, apt to be quarrelsome, mischievous, and irritable if thwarted. They talk a great deal in a boastful way, and are not so much happy as exalted and silly. They show a loss of finer feelings, making coarse jokes and eating ravenously, and having no realisation of their condition. They often adorn themselves fantastically and hoard rubbish.

Age and severe hereditary taint are supposed to be factors in the causation of chronic mania.

Treatment. The principal aims are to protect the patient from himself, from suicide in depression, and from exhaustion or the injuries resulting from impulsive violence in manic excitement, to secure sufficient sleep and nourishment, and to promote elimination. For the prevention of suicide, incessant supervision by trained nurses is essential; knives, cords, and all sources and instruments of harm must be excluded. Unless elaborate provision can be made at home, removal to a special hospital is necessary. Exhaustion may be forestalled by hydrotherapy (continuous tub and packs), nursing in the open air, confinement to bed, and the procuring of rest. Sleep, if not sufficient by these methods, may be increased by medinal, paraldehyde, chloral and bromide, and, if necessary, hyoscine. Feeding requires personal supervision from the nurse; tube feeding should be resorted to wherever refusal of food extends for forty-eight hours.

A study of the manic patient's utterances will often give clues to the stresses that have precipitated the illness, and will serve a useful purpose in the after-treatment when recovery has occurred and it is desired to give the patient a clear understanding of the cause, with an idea to preventing a recurrence. Reassurance will not appear to help a depressed patient at the time, but is, nevertheless, often a useful means of support. It has been claimed that psychotherapy of a more intricate kind may cure the attack; but it is usually wise to confine intensive psychotherapy to the intervals as a prophylactic measure.

The patient should be carefully supervised for some time after apparent recovery, in view of the chances of supervention of another phase.

INVOLUTIONAL MELANCHOLIA

This occurs, as the name denotes, in the involutional period of life, in the fourth or fifth decade, but cases with a similar symptomatology sometimes occur earlier. It is characterised by depression, with anxiety and apprehension, and delusions of a hypochondriacal, persecutory and nihilistic kind. There has been much discussion whether involutional melancholia is simply a manic-depressive psychosis occurring at the involutional period, and coloured by the changed outlook of later life. It has been asserted that there is frequently a history of previous mild attacks of a manic-depressive type, and that involutional melancholia exhibits all the principal symptoms of the manic-depressive psychosis. Moreover, the condition is recoverable in one-third of the cases. But involutional melancholia is worth considering separately, as the symptomatology and general course are sufficiently characteristic. An agitated type of depression is particularly common. The course is apt to be prolonged upwards of a year, and often over a number of years, but the prognosis is only indirectly vitiated by the degenerative physical changes of the period—arteriosclerosis and early senile changes, and the like.

Ætiology. The relation to external stress is specially clear in this group. A person who has succeeded in keeping stable hitherto breaks down at last in face of financial embarrassment, the discouragement of physical illness, the death of relations or a difficult domestic situation. Failure of potency, nominally discovered after a marriage late in life, is also in the male patients a not infrequent precipitating circumstance. The type of personality is also a feature, quiet seclusive people developing an involutional melancholic illness with disproportionate frequency. This throws light on the nature of some of the symptoms, especially the delusions of persecution, the negativism, the stereotypy, and the hallucinations that sometimes occur. Persons of a worrying and pessimistic description, who have always taken things seriously and have habitually "fought their battles over again," are also prone to develop an involutional depression.

The most characteristic symptoms however—delusions of poverty, of impending death and of bodily disease—are the result of the changing outlook of increasing years. An inherited taint of mental instability is significantly frequent. The sexes are affected about equally (51 per cent. of the patients are women).

Psychopathology. Understanding of the symptoms is aided by a consideration of the psychological alteration that normally accompanies advancing years. There is a diminution in energy, with a diminution in working capacity and a corresponding withdrawal of interest from the outside world to the self. Consequently an increasing interest is displayed in health, and death has to be contemplated as an increasing possibility. Cherished ambitions which have not been fulfilled have to be relinquished. Retrospection and misoneism become the habit (the “good old days”). From these conditions result increasing egocentricity, manifesting itself in the developed psychosis in a lack of emotional responsiveness, and actual peevishness. Hypochondriasis is in one of its aspects, an exaggeration of the preoccupation with health, while miserliness and delusions of poverty crystallise out from the financial anxieties. The failure of cherished ambitions for the patient himself or for his children leads to depression. Unwillingness to accept the fact of prospective dissolution appears in the psychosis as a fear of death, which is envisaged as full of terrors. An important further factor enters here, that ideas with a strong emotional colouring which the young healthy person may be able to keep in the background (by “repression”) are apt to break into consciousness, in a form all the more distressing because they have been distorted in the process of repression. Feelings of guilt of long standing about sexual and other misdeeds, real or only fantasied, give rise to delusions of unworthiness, and to apprehension of impending retribution (torture, damnation, etc.). The hypochondriacal delusions also rest not infrequently upon a feeling of guilt—that certain practices, especially masturbation, have ruined the patient’s health. The loss of interest in life, betokened by increasing egotism, implies also a longing for death; on the other hand, egotism resents the idea of death; and so these patients both seek for death and fear it, hence the combination of apparently contradictory symptoms like delusions of impending death and attempts at suicide. Projection of the loss of interest leads to nihilistic delusions—that nothing exists, that every one else is dead, that nothing is real.

Mental Symptoms. After a prolonged period of sleeplessness, restlessness, worry and headache, the patient becomes definitely depressed and usually apprehensive. With the depression go ideas of unworthiness, which often reach the intensity of delusions of unpardonable sin, ostensibly and characteristically over masturbation in youth. The depression may be well concealed by the patient: he may smile in conversation, and a short time afterwards attempt suicide. Increase in the depression and apprehension leads to continuous agitation, the patient pacing up and down, wringing his hands, biting his nails, weeping, moaning, pressing his forehead, sighing, digging his nails into his hands or throat, and pulling his hair. This may be continuous or intermittent with periods of quiet resignation, or actual apparent cheerfulness and even elation (rarely). There is often stereotyped activity, such as repeated requests for reassurance: “Are they going to take me away?” The patient shows delusions of impending persecution, often of a bizarre kind. He is to be shot, executed, roasted alive, etc.

The activity seems to depend largely on the nature of the delusional content. The above description applies to agitated depression. In others hypochondriacal delusions are the most prominent feature. Again, there is apt to be a grotesque kind of exaggeration, probably of metaphorical import. The bowels are rotten, the brain is dust, etc. In others a quiet inactivity goes with a nihilistic belief that all the world is dead, including (or excepting) the patient. In these sluggish inactive cases there may be some slowness in answering questions, the replies

being monosyllabic ; the condition closely resembles a manic-depressive psychosis. Others refuse to answer at all (mutism) and refuse food under the influence of delusions that they must not eat or speak (delusional control), often reinforced by hallucinatory commands to the same effect. There is usually no complaint of difficulty in thinking ; but some patients complain of perplexity—they cannot understand what they see.

The intellectual and sensorial functions are unimpaired except in persons with extreme agitation, in whom clouding of consciousness may appear, with terrifying hallucinations. A toxic superaddition is to be suspected here.

Suicide is a risk always to be borne in mind in these patients. It is more common in involutional depression than in any other psychosis.

The physical signs consist in emaciation, constipation, hyperactive kneejerks, and tremor of hands, as well as the physical accompaniments of advancing years, especially arteriosclerosis.

Course and Prognosis. There is often considerable fluctuation in the intensity of symptoms, and a patient apparently recovering may commit suicide. The course is prolonged, from at least many months to years. Recovery has occurred after eight years. The prognosis depends to some extent on the affective condition. The more the emotional disturbance of depression and anxiety fills the picture the more favourable the outlook. Peevishness and marked hypochondriacal preoccupation are said to be ominous. The presence of signs of senile cortical deterioration (memory defect) or of focal arteriosclerotic brain disease vitiates the prognosis.

Treatment. There are two guiding principles : the maintenance of physical strength and the prevention of suicide. Both require constant supervision ; the second means that the patient cannot be left alone day or night. Hence, unless he has means enough to allow of the provision of nurses day and night at home, treatment in a mental hospital is necessary. Rest in bed is indicated at first to facilitate nutrition. If the treatment can be carried out in the open air, restlessness is favourably influenced. Tube-feeding should be resorted to if the patient refuses food. Sleep can be secured in the usual way, but hydrotherapeutic measures are often contra-indicated on account of the patient's debility and active resistance. After the physical condition has been restored simple occupations should be devised. Sometimes these afford the first step in the patient's convalescence. Psychotherapy should usually be of a simple kind ; deeper probing may have disastrously upsetting results.

SCHIZOPHRENIC REACTION TYPES

(*Dementia Præcox*)

Schizophrenic patients compose 25 per cent. of the admissions to mental hospitals, and 40 per cent. of their permanent population. Kraepelin first collected the somewhat heterogeneous clinical material into one group and called them all "*dementia præcox*," but Bleuler's term, "*schizophrenia*," is to be preferred for various reasons : that many patients of this kind do not become demented, but recover, some completely, some partially ; that "*precocious*" is not a correct description, since neither does the condition necessarily occur early in life, nor is dementia, when it occurs, always rapidly attained ; and, finally, the root-meaning of schizophrenia, "*splitting of the mind*," is well adapted to describe what is sometimes considered to be the fundamental schizophrenic process, namely, a lack of the usual harmonious co-operation between the different mental functions. There has been a tendency to extend the term "*schizophrenia*" to cover nearly every psychosis, not of demonstrable organic origin, that could not be included under the manic-depressive psychosis ; but this is to be deprecated, although it is conventional and permissible to speak of schizophrenic symptoms complicating other psychoses (7).

Definition. Schizophrenia involves an alteration, commonly but not invariably progressive to a more or less profound and permanent deterioration in the patient's personality. The process reveals itself in change in feeling, thinking and behaviour, leading, on the one hand, to an attitude of apparent indifference to the external world, and, on the other, to an internal disorganisation of some of the mental processes, especially an incongruity between feeling and thinking, but with preservation of the intellectual and sensorial functions (memory, comprehension and orientation).

Ætiology. Incidence:—The condition first appears as a rule in adolescence; hence Clouston's term "adolescent insanity." Most cases are admitted to mental hospitals between twenty and forty, but they are not all by any means admitted at the time of onset. Schizophrenia has been reported as early as the age of four, and schizophrenic symptoms, colouring other psychoses, as late as the senile period. But schizophrenia in the sense described above is uncommon after forty-five. Males are affected more often than females (16 per 100,000 of population to 12·8 per 100,000). The fact that schizophrenia is more frequent in cities than in rural districts, and among the foreign-born population of the United States rather than among the native-born, gives some support to the conception of schizophrenia as a reaction to special stresses in adjustment. There is some in conclusive evidence that race and country of birth are predisposing factors, *e.g.* that Slavonic races are relatively prone to schizophrenic reactions.

Hereditary taint, in the form of psychoses, nervous diseases, alcoholism, epilepsy, senile dementia, abnormal character and suicide, prevails more in the ancestry of schizophrenics than in that of normal persons. Psychoses in antecedents and collaterals are especially frequent, being three times commoner than in the ancestry of normals. In addition to definite psychoses, abnormalities of temperament and character are significantly common in the blood-relatives of schizophrenics. The heaviest hereditary taint falls, however, on indirect (collateral) antecedents and in grandparents. Alcohol has little or no direct effect in producing a schizophrenic illness. Sometimes it acts as if it released latent schizophrenic tendencies; more often alcoholism is a symptom of schizophrenia, being resorted to by an individual already mentally ill.

Theories of the ætiology of schizophrenia are numerous. It has been suggested that schizophrenic psychoses result from a metabolic disturbance, from the presence of a toxin, from structural brain disease, or from focal sepsis, with consequent poisoning of the central nervous system. It has also been considered that the psychosis is a manifestation of a general "regressive atrophy" of the cells of the body generally, especially the small pyramidal cells of the brain and the cells of the endocrine glands, especially the testes. None of these theories has so far succeeded in establishing itself as the accepted explanation.

A constitutional predisposition probably exists. "This is held to be demonstrated on the physical side by the frequency with which "dysplastic" types of physique are found among schizophrenics, and also by the post-mortem finding that in the majority of cases there is a hypoplasia of many of the viscera, together with an unusually high incidence of chronic inflammatory lesions.

More directly related to the clinical manifestations of schizophrenia are the traits of personality which so often exist before the onset of frank schizophrenic symptoms. It has been recognised that a certain kind of person is more prone than others to develop schizophrenic symptoms. This type of personality has been called shut-in, schizoid, introvert, or narcissistic, terms which have different shades of meaning but refer to the same class of persons. The "shut-in" personality exists in approximately two-thirds of schizophrenic cases. These patients have always been shy, seclusive, reticent, hard to influence, sensitive and stubborn, with little interest in the pleasures and pursuits of the average person, but living instead in phantasy. Other peculiarities exist, such as shallow-

ness of emotion, lack of consideration for their environment, abnormal precision, or a poorly balanced sex-instinct.

How does the transition from a disposition of this kind to a full-blown schizophrenic psychosis occur? The psychosis is regarded as the result of a long-continued series of maladjusted reactions to environmental and inner stresses. The individual concerned, instead of facing his problems squarely, shirks them and adopts subterfuges ("substitutive reactions"), like amnesia, fault-finding, day-dreaming, prayers and other expedients. These subterfuges unfortunately tend to gain an automaticity of their own; they become more easily resorted to (habit deterioration), and ultimately more or less uncontrollable. The fact that the onset of a schizophrenic psychosis may be sudden is not against this view; the suddenness is equivalent to the rupture of compensation that may lead to the appearance of dyspnoea, oedema, etc., in a person whose damaged heart has hitherto performed satisfactorily. There is no question, on this theory, of any specific disease-entity; each individual is a case by himself. This does not preclude general similarities that make it possible to speak of a group of people having certain morbid reactions in common as belonging to the schizophrenic reaction-type; some people tend to become mentally diseased, as others develop normally, along one or other of several lines. Nor is the notion of inevitable dementia at all justified; it is merely that certain reactions are so pernicious as refuges that if they become habitual a reversal to normal is hardly possible (2).

Psychopathology. The disorder of thought, leading to the utterance of what often appears to be mere nonsense, is one of the clinically striking aspects of many schizophrenic patients. It is not such a surprising phenomenon when it is remembered that many of them have lost all desire to communicate with other people, and so need not make themselves understood. Hence they may, with satisfaction to themselves, use a language of their own. Furthermore, the disintegration of the personality that occurs in the schizophrenic implies that many feelings and tendencies that normally remain unconscious come to conscious expression, either directly, as, for example, simple delusions of grandeur, which are the naïve expression of ambitious day-dreams common to all men, or delusions of being loved, which are the counterpart in women; or indirectly, as, *e.g.* hallucinations or delusions of persecution, which are the joint result of unconscious tendencies and of an attempt to repress them, with the consequence that these tendencies reach only a qualified distorted expression; *e.g.* homosexual liking for another person may reach conscious expression as a delusion of persecution (dislike) by that other person.

Another quality that makes the schizophrenic's mental processes seem so disorderly is the symbolism in which his thoughts are so often disguised. The disguise may be an attempt at repression, *i.e.* refusal to recognise certain tendencies within himself; or it may be regarded as a regression (return to an earlier stage of development) to a type of thinking found more prominently among primitive races. Lack of clearness in thinking is also responsible for some of the disorderliness of the schizophrenic's statements. Any one becomes slovenly in the expression of his thoughts who does not continually test them against reality. In his sensitive self-centredness (introversion), the schizophrenic cannot bear to do so; his illness in one sense is the result of a turning away from the unpleasant reality of an unfriendly world to a world of phantasy where everything is as he wishes it, where he receives "perfumes and flowers that fall in showers, that lightly rain from ladies' hands" (6).

Mental Symptoms. It is usual to describe four main types of schizophrenia—the simple, the hebephrenic, paranoid and catatonic types—according to the relative preponderance of certain symptoms. But there is no decisive line of demarcation. All of them are characterised by a loss of interest in the external world of reality, and by a corresponding absorption of the patient in his own

inner experiences; all of them show also an apparent discrepancy ("intrapyschic ataxia") between emotional and thinking processes (a discrepancy which may perhaps be more apparent than real) and a disorder of the process of thought itself (*vide* "Psychopathology"), which makes the utterances of these patients seem incoherent and absurd. There is usually a preliminary period of vague uneasiness and gradually increasing change in personality and behaviour, which may be simply the further development of the traits already mentioned. The patient is less and less inclined to mix with other people, and he becomes inactive, sitting for hours perhaps doing nothing. On the other hand, impulsive outbursts of activity may occur, *e.g.* in the form of a fugue or of personal violence. He neglects his appearance; when remonstrated with he is irritable and even dangerous. He complains of unpleasant feelings, especially in his head, and makes odd, unfounded remarks, often to the effect that certain people are watching him or are interested in him in a special way (ideas of reference). True depression of spirits is often felt, and at this stage it is sometimes difficult to distinguish the condition from an attack of cyclothymic (manic-depressive) depression. On the other hand, an elation of a thin and unconvincing kind may be the only mood-change, and this may go, for example, with an attempt to write high-sounding prose, or to construct a fantastic philosophical or mechanical scheme. Insomnia and disturbances in the general health (loss of weight, etc.) accompany the mental symptoms. Sometimes the onset is sudden, especially after acute infections. The catatonic form is apt to have a more dramatic onset than the others.

Schizophrenia Simplex. The principal feature of this type is the falling off in external interest, the patient becoming solitary and apparently preoccupied. There are often illusions and hallucinations of a fleeting kind, but commonly the impression is of such impoverishment of energy and interest that even autistic activity is reduced to a minimum. Ultimately the patient sinks into a quiet, docile state, in which he may be capable of routine work of the simplest kind under supervision. Such persons may remain outside of institutions, and furnish a proportion of life's failures following upon early promise. They swell the ranks of the idle and unemployable and of tramps and prostitutes.

Hebephrenic schizophrenia is characterised especially by the fantastic and fleeting nature of the delusions, the prominence of hallucinations, the striking incoherence of thought, and the emotional deterioration showing itself in apathy (indifference to environmental stimuli) and disharmony of thought and emotion, so that for example, alarming and distressing ideas are received or related in a matter-of-fact way. Alternation of depression and excitement, the latter often with wild impulsive and suicidal activity, is also characteristic. Mannerisms (fantastic ways, *e.g.* of eating) and stereotypy of speech, movement, and posture (tendencies to repeat certain phrases and motions and to maintain awkward bodily attitudes), silly laughter (*i.e.* laughter without apparent justification), and fantastic self-decoration, are all frequent. The persons in whom this type develops have often been imaginative and unpractical, romantic and artistic, lacking in self-confidence, suggestible, timid, unsociable, with narrow interests, but kindly and mildly cheerful. The general impression in the fully developed condition is one of incoherent fatuity in a setting of complete disintegration of the previous personality.

The paranoid form is common in persons in whom definite schizophrenic signs develop after thirty years of age. The relationship of paranoid schizophrenia to paranoia and paraphrenia is best expressed by arranging the conditions in a series—paranoia, paraphrenia and paranoid schizophrenia—in that order of increasing disintegration of the mental life. The characteristic signs of paranoid schizophrenia are the prominent delusions, the lack of systematisation (in contrast to paranoia), their fantastic, transient and changeable nature, and their association with hallucinations, often of a fatuous kind, and like the delusions themselves, usually persecutory or grandiose in nature. The other signs and

symptoms are those held in common with the other forms of schizophrenia. The type of personality in whom paranoid schizophrenia ultimately develops is commonly stubborn, seclusive, rigid, "bending the facts rather than to the facts," and self-conscious. An appearance of self-confidence marks in them a decided lack of it. Often in childhood these people have been unusually disobedient, not open to advice or correction, and insistent on having their own way. Others have been bashful and retiring, lacking in initiative and always on the defensive.

Catatonic schizophrenia is especially characterised by stupor and negativism (resistance to impressed movements or actual carrying out of an action opposite to that requested) alternately with outbursts of impulsive excitement. Stupor comprises mutism and general immobility, together with lack of response to stimuli, so that the patient does not attend to the calls of nature, and even saliva is allowed to collect in his mouth until it is putrid. Stupor is commonly associated with, and may in itself be a manifestation of, negativism, including the refusal of food and resistance to passive movements. On the other hand, the limbs may remain in any position in which they are placed by an observer (*flexibilitas cerea*), and may not fall, even under the influence of gravity. This may be regarded psychologically as the opposite of negativism. Similarly, the patient may obey in apparently automatic fashion whatever he is told to do (command automatism), and may repeat automatically what he has heard (echolalia), or imitate exactly whatever movements he sees others perform (echopraxia). Perseveration is exhibited not only in the maintenance of postures of the limbs, but also in the classical *schnautzkrampf*, the patient holding his lips pursed like a pig's snout. From this condition of stupor and neuro-muscular tension there is often a gradual or rapid change to wild excitement, in which the patient is impulsively violent, suicidal and homicidal. In this condition he may go on for days or weeks, taking no heed of the injuries he inflicts on himself, tearing off dressings, neglecting food or eating it ravenously, talking incessantly and sleeping little. Such attacks of over-activity are often short-lived, the patient relapsing quietly into stupor.

It will be seen that all the symptoms of the stuporous phase of this condition can be considered as various expressions of negativism, in the sense of an attempt to shut out the external world, and of its opposite, extreme suggestibility (echolalia, etc.), together with perseverative phenomena (stereotypies).

Physical signs are more prominent in the catatonic than in the other varieties, but are not characteristic or significant in any way except of general physical unfitness. Especially common is cyanosis of the extremities, sometimes with œdema (the result of immobility). The tendon reflexes are usually very active. There are also constipation and retention of urine and saliva (all to some degree negativistic phenomena).

Course and Prognosis. The following statements are of general application; individual cases produce surprises. The majority of schizophrenic patients deteriorate, quickly or slowly, to a chronic deep dementia. Others recover to, or are arrested at, a state of mild dementia, consisting of more or less apathy, with poverty and disorder of thought and slight oddities of behaviour. These and others make what is called a "social recovery"—they are sufficiently well to live outside hospital, although recognisably not fully normal. The outcome is related to some extent to the nature of the symptoms. When there is much confusion the prognosis is less hopeless than when the sensorium remains clear. The more profound the emotional symptoms in the form of depression or elation—i.e. the more the picture resembles that of a manic-depressive psychosis—the more hopeful the outlook. Patients in whom the onset has been acute have a better chance of recovery than those with long prodromata. (The probability of overlooking the latter has to be remembered.) The previous personality has to be weighed—the better "stuff" a patient is made of the better his chances of

a favourable adjustment. Patients with a catatonic schizophrenia of acute development show a higher recovery rate than occurs with other types. Previous attacks with remission suggest the possibility of a further remission, but the general tendency in remitting cases is to a progressive inadequacy.

Prevention by mental hygiene in early life suggests itself as the most likely line of treatment, in view of the volume of evidence in favour of predisposition by faulty attributes of temperament and character. Parents and educators must be instructed as well as the children. Foresight in planning a suitable career instead of the present largely hit-or-miss method is likely to lessen the chances of maladaptation.

Treatment is in a very unsatisfactory state. When a recognisably schizophrenic condition has established itself, institutional treatment is usually necessary, on account of the odd and sometimes even dangerous behaviour, and the patient's neglect of his own physical needs. The *régime* of hospital, with its insistence on cleanliness, appointed meals, regular evacuations and sleep, helps not only the general health, but corrects deterioration in habits to some extent. Occupation of a suitable kind (rug-making, weaving, basket-making, etc.) helps to stimulate the flagging external interest and to re-establish self-respect. The more the physician can get into touch with the patient, and enter into his perplexities, the more hope there is. Precautions must be taken against impulsive suicidal and homicidal outbursts and attempts at self-mutilation (*e.g.* self-castration as expiation for some sin, real or phantastic). Tube-feeding has sometimes to be resorted to, either by stomach-tube or (in very resistant patients) by nasal tube. Isolation in a single room is only to be resorted to when the patient is too disturbing to others. The control of excitement demands isolation and skilled nursing (male nurse for excited male patients), with, if necessary, sedative and hypnotic drugs and, rarely, mechanical restraint to prevent self-injury. It has to be remembered that measures such as these can only legally be carried out in licensed houses and certified institutions, recognised by law for the purpose. Special indications in the physical health (teeth, tonsils, sinuses, or any other foci definitely known to be infected) should be attended to. The general physical unfitness that has been demonstrated in such patients calls for exercise, hydrotherapy, and the open air. If sleep can be arranged out of doors so much the better.

Empirical methods of all sorts have been tried—the induction of an aseptic meningitis, of febrile conditions (by malaria, nucleinate of soda) and of prolonged sleep (with trional or somnifen, etc.). Protein shock, vaccines, endocrine preparations, calcium, and testicular extracts have all been tried with little evidence of success. Some put thyroid medicinally in; others surgically take it out, in both cases without specific effect.

PARANOIA AND PARANOID STATES

The essence of paranoia, paranoid states and paraphrenia is the presence of delusions in a setting of clear consciousness. These conditions were previously known as "delusional insanity." *Paranoia* was defined by Kraepelin as consisting in the insidious development of a permanent and unshakable delusional system resulting from internal causes, accompanied by perfect preservation of clear and orderly thought, will and action. Hallucinations are absent. Recovery does not occur, but neither does dementia. *Paranoid states*, *i.e.* states characterised by delusions, are sometimes of acute onset, often transitory, often precipitated by some exogenous factor (infection, war, imprisonment, operation). The delusions do not reach the extreme systematic development of paranoia; but hallucinations may be present (hallucinatory paranoid states), and their content harmonises with that of the delusions.

Ætiology. The condition becomes obvious usually in middle life, and in

males more commonly than in females, in the proportion of seven to three. Paranoia itself accounts for only about one in 100 admissions to mental hospitals, but the condition is more frequent than the figures would indicate, a number of patients succeeding in preserving a sufficient social adjustment to remain outside of hospital. While paranoid symptoms or even a full-blown paranoia sometimes become apparent in relation to organic disease, as if the injury to the personality as a whole uncovered or released underlying trends, paranoia itself, in the accepted sense of the term, is found in persons organically healthy in every way. The rôle of heredity is uncertain. It is said that in the descendants of paranoics, paranoid schizophrenia is apt to appear.

The evidence is much stronger for the existence of peculiarities of temperament and character in the patient himself long before the appearance of the psychotic symptoms. The "paranoic constitution" has been described as one with a tendency to see always a biased meaning in things and to be suspicious. There is a failure to recognise and admit adverse facts: such people are always in the right, haughty, vain, sensitive and easily offended, sulky, irritable, and often very ambitious, with a high opinion of their own worth and deserts. Some are obstinate and revengeful, others over-scrupulous and over-conscientious and self-centred. Some have the notion of being born for something special; others cherish a phantasy of exalted birth, or of being loved by some one higher in the social scale. Some, being sexually dissatisfied, develop a morbid jealousy of the spouse; others show principally a morbid concern about health (hypochondriacal preoccupation). In the psychoanalytic view, the essential determinant, alike of the constitution and of the subsequent psychosis, is a repressed homosexuality; in the psychosis, the repressed tendencies are projected (*i.e.* attributed to people in the environment and disowned by the patient) in a disguised form as delusions of persecution (10).

Mental Symptoms. It is out of some such personality as a rule that a paranoic psychosis develops, usually with insidious slowness. There is often a prodromal stage, in which the patient complains of nothing but general malaise, or of peculiar sensations, not yet attributed (openly at least) to any external agency.

Commonly there follows a stage of ideas of reference: people are looking at the patient, or talking about him; small actions in the environment are misinterpreted; people cough as they pass him, or cover their mouths with their hands, etc. From these the passage is easy to delusions, which connect up and explain all that the patient believes he has observed. The delusions are worked up into a more or less coherent system. There is a plot against the patient on the part of the Masons, or the Roman Catholics, or Scotland Yard. Gradually the delusions extend to cover a large part of the patient's everyday experiences, and no amount of persuasion makes the slightest impression on the patient's unshakable belief in his interpretations. The delusions are persecutory and grandiose (megalomaniac), but frequently the former exist apparently alone; they practically always precede the development of grandiose delusions, which may therefore be looked on as compensatory to the persecution. The patient must be someone important, else he would not be persecuted. Out of this egotistical self-estimation develop notions of royal birth, of divine mission, of great wealth, and the like. The patient believes he is a prophet, or a prince, or the heir to millions, or that he has invented a *perpetuum mobile*. A number of crank inventors belong to this class. The mood varies. Memory and the intellectual functions generally are intact. Pseudo-memories, in the form of falsifications of events in the patient's life, become increasingly numerous as time goes on, so that it is impossible to be sure that a patient's story gives a reasonably accurate account of the beginning of his psychosis. He misinterprets events long past in the light of his delusional beliefs, and suddenly sees meanings in events which had puzzled him at the time. The behaviour may be outwardly unaltered, the

patient passing for socially normal so long as he is not speaking of his delusions. But not infrequently he betrays himself by attempts to interview M.P.'s and other personages, by letters to editors or (much more rarely) by assaults on persons whom he blames for the persecution. Frequent changes of occupation or residence, or emigration to another country, are the expressions of an attempt to flee from persecution. Three stages of the condition were in fact described: "Il fuit; il se défend; il attaque"; but the sequence is not at all invariable. Delusions of jealousy (unfaithfulness of spouse) are less common. Hypochondriacal delusions are frequently present, but are not predominant.

"Abortive" paranoias or "*formes frustes*" have been recorded. These are sometimes mild manic-depressive conditions with a paranoid colouring: at other times they are the response of a paranoid personality to a sudden stress, the delusional symptoms subsiding when the stress disappears.

There are no characteristic **physical signs**.

Course and Prognosis. The condition is chronically progressive. Recovery in a full-blown case is practically unknown. There is little tendency to deterioration in the sense that, although the delusions may increase and influence conduct more, intellectual operations on neutral topics are intact and the patient takes care of his outward appearance.

Treatment is a matter of judicious arrangement. To attempt to argue the patient out of his beliefs is fatuous. He must be listened to and his confidence gained as far as possible. It is then feasible to give some practical advice calculated to prevent the patient coming into open conflict with society, but without letting him feel that his ideas are profoundly disbelieved. The provision of occupation of an interesting kind is very necessary. It is advisable for this purpose to keep the patient in his own environment, unless there is a reliable hospital or home where truly adequate interests and occupations are provided for the patient. There are a few cases where, on account of anti-social trends of a violent kind, removal to a mental hospital is obligatory. Certification as insane is then imperative, since the patient's lack of insight prevents his realising the necessity for safeguarding.

PARAPHRENIA

This has been distinguished from paranoid schizophrenia on the one hand and paranoia on the other. It occurs at a later age than paranoid schizophrenia, as a rule (after about thirty-five), and the deterioration in affect, the discrepancy between affect and thought, and the incoherence in thinking, are much less pronounced. The delusions are more consistent with each other than in schizophrenia, but, on the other hand, are more fantastic and less carefully knit together than in paranoia. The paraphrenic suffers from hallucinations, and the paranoic is supposed classically not to do so. But all these distinctions break down in practice. The course is more slowly deteriorative than that of paranoid schizophrenia.

ORGANIC REACTION TYPES

These comprise the following:—

(A) Psychoses with toxins or infections. Toxins: (i.) Endogenous, *e.g.* uræmia, eclampsia, acute yellow atrophy; (ii.) Exogenous, *e.g.*, alcohol, opium (and its derivatives), cocaine, bromides, etc., metals (lead, etc.), gases (carbon monoxide, chloroform, etc.). Infections: (i.) General—pre-febrile, febrile and post-febrile deliria from bodily infections; (ii.) Local brain infections—syphilis: (a) general paralysis, (b) meningeal and vascular syphilis; encephalitis, including epidemic encephalitis; meningitis; abscesses.

(B) Psychoses with primary degenerative brain changes: Senile dementia, pre-senile cerebral degeneration, Alzheimer's disease, presbyophrenia, arteriosclerotic brain disease, Huntington's chorea.

(C) Psychoses with general metabolic deficiency: Pellagra, myxoedema, cretinism.

(D) Psychoses with brain trauma: Traumatic delirium, constitution, mental enfeeblement, behaviour disorders.

(E) Psychoses with other brain diseases: Brain tumour, multiple sclerosis, thrombosis, embolism, etc.

(F) Psychoses with chronic general diseases: Cardio-renal disease, pernicious anæmia, etc.

All these except infection exhaustion states, presbyophrenia and Alzheimer's disease have been described in the preceding sections.

Symptoms. The essential symptoms of the organic reaction-type in general are those attributable to disease, toxic or structural, of the brain. They are principally defects of the sensorial and intellectual functions, and consist of impairment of memory, attention, perception, comprehension, and retention: recent events are rapidly forgotten; there is difficulty in activation of old memories; fluctuation in the level of attention, and probably diminution in the span of attention, so that the patient cannot hold isolated facts simultaneously before his mind; difficulty in comprehension, new events not being readily assimilated with the old, or with each other; and, in consequence of all this, lack of social capacity.

Secondly, there is frequently affective disorder in the form of emotional instability, the patient laughing and weeping without sufficient cause or being explosively irritable. There may also be depression, or anxiety, not the direct result of the brain-disease, but the outcome of the patient's realisation that he is ill. More rarely there is euphoria, as in G.P.I. and disseminated sclerosis, an anomalous result perhaps related to the special toxins.

Thirdly, behaviour disorders, out of keeping with the previous personality, may appear, doubtless in part as a result of release from higher control (failure of cortical inhibition). In this way indecent exposure, sexual misdemeanours, petty and fatuous thefts, foolish extravagance, violent assaults, and the like, may arise episodically.

The typical acute organic reaction is a delirium. In this attention fluctuates with extreme rapidity; perception is so much impaired that disorientation is usually complete; illusions appear; and hallucinations are common. When emotional disturbance occurs, it is commonly, but not invariably, fear.

INFECTION EXHAUSTION PSYCHOSES (*including Neurasthenia*)

Infection exhaustion psychoses include a variety of symptom-pictures, accompanying or following acute infections, poisoning by an exogenous or an endogenous toxin, hæmorrhage and extreme physical stress of any kind. The infection exhaustion psychoses, properly so-called, belong to the organic reaction-type; but similar causes, in predisposed individuals and sometimes in persons in whom no predisposition is discoverable, may release or activate a mental disorder of a manic-depressive, schizophrenic or paranoid kind. In these instances, however, there is apt to be an admixture of organic symptoms (*e.g.* disorientation out of proportion to the intensity of a manic excitement) which will suggest to the observer an infective or organic origin of the condition.

There is no specific correspondence between the types of infection or other stress and the type of psychosis produced. Any type of infection, etc., may be associated with any type of psychosis, the result being dependent largely on the psychic constitution of the individual attacked. When infection is the cause, mental symptoms may occur either in the pre-febrile, febrile or post-febrile stage, and there is no hard and fast distinction between the symptoms at any of these stages. The commonest reaction is delirium, but a hallucinosis (without disorientation), a catatonic state (either with or without hallucinosis), and stupor may also occur, and at any stage. Intellectual enfeeblement, amnesia, some-

times of the Korsakow type, apathy and depression occur in the post-febrile stage. Such conditions are one of the types of "neurasthenia," as that comprehensive word has been used, the term being applied especially when, in addition to depression or apathy, there are fatigability, mental and physical, headache, vague pains, and anorexia with loss of weight. Influenza is especially apt to be followed by this type of depression, in which suicidal attempts are not uncommon and convalescence is very slow.

The characteristic delirium of the febrile period is ushered in by restlessness and insomnia, with terrifying dreams and feelings of numbness and confusion in the head. This is followed by the symptoms of delirium proper—disorientation, failure of attention and comprehension, inability to sustain a train of thought, and hallucinations, often but not invariably accompanied by intense fear, which may prompt assaults in self-defence or homicidal attempts at escape. Violent psychomotor excitement sometimes ensues, and in severe cases coma. In the post-febrile stage a "collapse delirium," with extreme prostration as well as hallucinatory phenomena and restlessness, has been described.

The physical signs are those of the provocative physical condition. Examination of the blood may show an acidæmia, and sometimes there is nitrogen retention.

Treatment should be directed to discovering the underlying physical condition and to combating any infection, general or focal, which may be found. Symptomatic treatment consists in rest in bed, preferably in the open air; hydrotherapy; adequate feeding (by stomach-tube or nasal-tube if food is persistently refused) with milk, cereals, sugar and fruit-juice; elimination by the bowels (calomel, followed by milder medicaments); alkalis well diluted by mouth or bowel; and where toxæmia is profound, physiological salt solution by the bowel (Murphy drip) or even intravenously.

"*Central neuritis*" (Meyer) denotes an acute inflammatory change in the cerebral neurones, occurring as a terminal stage in a variety of conditions, especially pellagra. Clinically there are spastic paralysis with contractures; confusion, often with hallucinations, illusions and noisy restlessness. The confusion merges into coma, and death is the inevitable termination.

PRESBYOPHRENIA

This is a condition of cortical degeneration occurring in middle life and in the pre-senile period, especially in women. It is characterised clinically by progressively complete failure of retention, so that recent memory disappears, and therefore in the course of time much of the more remote memory also; by lack of comprehension, and consequent increasing disorientation; by lack of insight; and by a fatuously happy mood with facile laughter and occasional irritability. The gap in memory is commonly filled by invention (confabulation), again without insight. There is a deterioration in the general behaviour: the patient no longer takes ordinary care of her clothes, etc., and, although in some cases still a young woman, she becomes incapable of the simplest household responsibility. She is very talkative, rattling on in an incomprehensible way, the question that prompted her to begin to talk having been quite forgotten. Cases of this sort not infrequently end with focal signs, *i.e.* with a clinical picture indistinguishable from Alzheimer's disease.

ALZHEIMER'S DISEASE

This depends upon a degenerative change in the brain cortex, beginning usually in the pre-senile period, *i.e.* in the fourth decade (sometimes as early as the thirties). There is a diffuse cortical atrophy of senile type. Microscopically there are wedge-shaped cortical foci showing loss of cells, from gradual occlusion of the smaller blood-vessels which run from the meninges into the cortex. The occlusion of these vessels results in numerous small hæmorrhagic

softenings, or in atrophic areas. Gross focal lesions such as occur in arteriosclerosis are wanting. The lost nerve-cells are replaced by whorls and tangled masses of fibrils (which are held to be the intracellular fibrils of the degenerated nerve-cells).

Clinically the patient exhibits loss of memory, recent and remote, with impairment of comprehension and lack of insight. Focal disturbances such as aphasia appear early. Indeed, the clinical picture of Alzheimer's disease is that of presbyophrenia plus focal signs. Later the patient becomes restless and talkative, singing and laughing. The aphasia reaches a profound degree, speech becoming a senseless jargon. Walking becomes impossible. Other focal signs appear (paralysis of the limbs). Epileptic attacks occasionally occur, and the pupillary reactions may be lost. The course is progressive, but slowly so, towards death.

Pick's Disease is clinically indistinguishable from Alzheimer's disease, but is characterised by a more definitely familial incidence, brain atrophy that falls more in certain areas (frontal and temporal) and comparatively greater loss of white matter.

PSYCHOPATHIC REACTION TYPES

Temperamental instability (sometimes called "constitutional psychopathic inferiority") is a factor common to the predisposition to many mental illnesses; but in some persons it reaches such a pitch in itself that, even apart from any incidental complicating mental illness to which the instability renders its possessor prone, it may be a serious factor in producing maladaptation and general inefficiency. When combined with some degree of intellectual defect, it is still more prone to produce failure in life, alcoholism, drug addiction, or actual anti-social behaviour (suicidal attempts, delinquency and crime). Persons suffering from this degree of temperamental instability, and being thereby far too readily depressed, just as they are too easily elated or made suspicious (with ideas of reference) or antagonistic or rebellious, are more prone than their normal neighbours to develop definite mental illness when faced with some difficulty in life; but just as such psychoneurotic or psychotic episodes are more easily provoked in them than in normals, so these episodic manifestations more readily subside. Such individuals often betray themselves, even on superficial inspection, by their frequent change of occupation and by their lack of concrete plans. Some of them have great aims, but all of them lack persistence.

In a number of them much improvement can be effected if they are treated early enough. There is evidence that in some at least the instability is not innate, but acquired in response to early influence of environment, especially of the family. Apart from intensive psychotherapy, the treatment is one of practical arrangement and, as far as possible, safeguarding. The selection of the most suitable occupation after an examination of the patient's abilities, intellectual or manual, is especially important. Any one finds it more easy to stick to a job he is naturally fitted for. This, together with sufficient social and other provision and more or less supervision by some one in whom the patient has confidence, is the best prophylactic of serious consequences of the instability. When the temperamental instability has brought the patient in contact with the law, full use should be made of probation, coupled with investigation into the circumstances and motives of the delinquent act, and a subsequent attempt to place the patient in a suitable environment.

In children and adolescents temperamental instability produces special problems which are at the same time more hopeful than at a later age. In such patients of the hospital class full use should be made by the practitioner of the out-patient clinics (psychiatric and pediatric) of general hospitals, which are equipped to deal with them; of child-guidance clinics, of school authorities, social workers and of the appropriate charitable organisations, as well as, in delinquency, probation officers, some of whom are now specially trained in this branch

of the work. Instruction of the parents is an important part of the treatment. Faulty attitudes of over-solicitude, etc., must be corrected after their influence on the child has been explained.

"*Folie à deux*," or "communicated insanity," is the term applied when two persons closely associated with one another suffer simultaneously a psychosis in which one member of the pair appears to have influenced the other in his delusional ideas. The condition is not, of course, necessarily confined to two persons, and may involve three or even more ("*folie à trois*," etc.). It is commonest in persons living secluded lives and in elderly people. Husband and wife, brother and sister, or parent and child, or friends of the same sex living closely together are the usual subjects of the condition. It is commonly a paranoid one—delusions of persecution, sometimes mingled with delusions of grandeur (royal birth, etc.). Occasionally there is a collective hallucinosis (*e.g.* of infection by insects which are seen). One or other patient has the predominant rôle and plays unwittingly upon the suggestibility of the other, who may be over-suggestible either from affection, ignorance or hysteria.

MENTAL DEFICIENCY

(*Amentia*)

Mental defect, or "amentia," as it is often called in this country, refers to defective intellectual endowment, existing either in the germ-plasm (primary amentia) or acquired as the result of intercurrent disease at any time after conception (secondary amentia).

The causes of mental defect are mainly these: (1) Heredity. There is a form of defect which is heritable, probably as a Mendelian recessive. (2) Blastophoria: parental alcoholism, syphilis, tuberculosis, or debility from any cause, devitalising the germ-plasm. (3) Birth injury. (4) Disease in early life, especially toxic and inflammatory conditions of the brain (meningitis, encephalitis, etc.).

Physical accompaniments are common, especially in the primary form, as the so-called "stigmata of degeneracy." These consist in anatomical malformations—of the skull, as microcephaly, macrocephaly, hydrocephalus, steple-skull, etc.; of the palate and teeth; and of the eyes and ears; and in physiological disturbances (usually dependent on anatomical lesions), such as paralysis, tremor, stammering, clumsy speech and choreiform movements, strabismus, nystagmus and epileptic attacks.

It is usual to classify mental defectives according to the degree of their defect. In the Mental Deficiency Act of 1913 they have been divided into idiots, imbeciles, feeble-minded and moral imbeciles (14).

The criteria which have been used clinically and legally (as in the definitions given below) have been principally those of conduct and capacity, *e.g.* whether the patient could learn at school and whether and to what extent he was afterwards capable of earning his own living. But in 1906 Binet and Simon, two Parisian psychologists, devised "tests of intelligence" which, with various modifications, have since been much employed to facilitate more accurate diagnosis and classification. These tests enable a "mental age" to be assigned, according to the number of tests passed. Adult defectives having a mental age less than that of a normal child of two are idiots; those with a mental age between three and seven correspond to imbeciles; and those above seven, but not more than about ten in mental age, are feeble-minded. The upper age-limit for feeble-mindedness depends a good deal on associated temperamental factors. A degree of mental development which would allow its possessor to earn a living and keep a place in the community under ordinary conditions may be insufficient for these purposes by reason of associated temperamental instability, which, along with the intellectual defect, renders the patient legally and socially classifiable as feeble-minded. Defectives of all grades are therefore further divisible

into "stable" and "unstable." The mental age of the average normal adult on the above scale is now assumed to be fourteen years. To make comparison at different ages possible it is necessary to express the mental age as a function of the chronological age, and the expression $\frac{\text{mental age} \times 100}{\text{chronological}}$ is known as the "intelligence quotient," or I.Q. On the whole, the latter remains remarkably constant throughout the development of a given individual. To reach an approximate estimation of an individual's capacities, it is necessary not only to apply tests of intelligence, so called, like the Binet-Simon tests, but tests of practical ability, such as "performance tests," "maze tests," and tests of mechanical aptitude, for all of which special apparatus and formulæ have been devised. Tests of temperament are much more difficult; the best criteria of temperament are obtained from the history (12) (15).

The following is the classification according to the **Mental Deficiency Act of 1913**, with the corresponding **symptoms**.

Feeble-minded or Morons "Persons in whose case there exists from birth or from an early age mental defectiveness not amounting to imbecility, yet so pronounced that they require care, supervision and control for their own protection or for the protection of others, or, in the case of children, that they by reason of such defectiveness appear to be permanently incapable of receiving benefit from the instruction in ordinary schools" (Mental Deficiency Act, 1913). By the Mental Deficiency Act of 1927, "early age" was defined as not exceeding eighteen years.

"Stigmata of degeneracy" are frequent in the feeble-minded. Delay in learning to walk and to talk is the rule in early childhood. Enuresis and sometimes faecal incontinence up to a late age are more frequent than in the normal. There is also abnormal susceptibility to infections. The mental functions show distractibility of attention, which itself makes learning difficult, in addition to a defect of comprehension and of ability to reason abstractly. The defect of association capacity which underlies the defect in comprehension is responsible, together with a lack of persistent emotional drive, for a defect in imagination, which even in the adult feeble-minded is childlike in its simplicity. The males do not get much beyond the stage of picturing themselves as engine-drivers, and the day-dreams of the girls do not surpass the fairy-princess level. Emotionally, many are stable and docile, but their very docility makes them easily led into delinquency, illegitimacy or actual crime. A few are unstable, passionate and uncontrollable. At school the feeble-minded, even at the best, hardly perform work equivalent to the average Standard II. The lowest grade of feeble-minded are incapable of any scholastic attainments at all: they cannot master words of even one syllable, or perform the simplest addition or subtraction. Fortunately, in the higher grades many are capable of being useful at handicrafts of a simple kind, and of supporting themselves in adult life; and a considerable proportion of those classed as feeble-minded at school cease to be so classed as adults, since they prove to have sufficient manual ability to earn a living and sufficient common-sense to manage their lives on a simple level. The corresponding mental age is seven to ten years.

Imbeciles are "persons in whose case there exists from birth or from an early age mental defectiveness not amounting to idiocy, yet so pronounced that they are incapable of managing themselves or their affairs, or, in the case of children, of being taught to do so." Imbeciles as a class show a higher incidence of stigmata than do the feeble-minded, since a large proportion of them belong to the group of primary aments. They are clumsy in movement and fatuous in expression. Their vocabulary is very limited, and scholastic ability almost *nil*. Some are exceedingly restless. The unstable variety may exhibit simple cunning, violent anger, jealousy, careless habits, immodesty and unrestrained masturbation. Not a few are childishly vain. The corresponding mental age is three to seven years.

Idiots are "persons so deeply defective in mind from birth, or from an early age, as to be unable to guard themselves against common physical dangers." In idiots physical degeneracy reaches such a degree that they may be recognised at a glance. They are stunted, misshapen, suffer from various paralyses, and if they can speak at all, can utter only a few words, and then in a clumsy way. They do not attend to the calls of nature, but constantly wet and soil themselves. They do not eat, but rather "wolf" their food. Some are destructive of everything within their grasp. Many of them are bedridden of necessity from locomotor defect; those that can get about by themselves are exceedingly clumsy. Even more than imbeciles they are subject to infections, and they fortunately, as a rule, die young. Intellectual processes are virtually absent. Only the most primitive emotions—rage, cruelty, fear and bodily pleasures—are evinced. The corresponding mental age is less than two years.

Moral imbeciles are "persons who from an early age display some permanent mental defect coupled with strong vicious or criminal propensities on which punishment has had little or no deterrent effect." The term "moral imbecile" is unfortunate, because in a considerable proportion of cases so designated there is little or no intellectual defect. The morbidity is in the emotional sphere. Such persons appear to have none of the emotions that are such important constituents of the moral sentiments. They lie, steal, drink to excess, are sometimes violent and even cruel without provocation, and are unprincipled and untrustworthy in every way; yet they never at any time show any compunction or any genuine feeling of regret. Punishment has no effect in mending their ways. Treatment is mainly by way of control. It is well for their relatives if "moral imbecility" is diagnosed early (although it should not be diagnosed earlier than late childhood), and steps taken to segregate the patient by certification under the Mental Deficiency Act. Later they are still more difficult to deal with. The principal hope of getting control of them then becomes this: that they should commit some crime and so be dealt with by imprisonment, or that they should develop a psychosis and become certifiable under the Lunacy Act.

Pathological Classification. Defectives are also classified as follows: (1) *Primary aments*, who fall into three main groups: simple, microcephalic and mongolian. (2) *Secondary aments*, who are divisible into (a) those having gross cerebral lesions—amaurotic, syphilitic, hydrocephalic, porencephalic, sclerotic, paralytic, and other after-effects of gross inflammatory or vascular lesions, such as epidemic encephalitis; and (b) those without gross cerebral lesions, but who suffer from general arrest of neuronie development, epileptic, cretinous, or nutritional. Many of them have been described in earlier sections of this book. The result of disease of sense-organs and corresponding lack of cerebral development ("isolation amentia") is dealt with below. All of these types of amentia may exist in any of the degrees of feeble-mindedness, imbecility and idiocy.

Below is a description of certain well-defined types:—

Microcephalic amentia is the term applied to a condition in which the mental defect is associated with an obviously small skull, commonly less than 17 inches in circumference. But if the shape of the skull rather than the skull size be made the criterion, patients with skulls of a circumference 2 inches or so more than this may be included. The typical pointed or "bird-like" shape is produced by recession of the frontal and flattening of the occipital region, with which are associated hypoplasia of the cerebral hemispheres and immature development of individual neurones and fibres. There are imperfect development of gyri, and local areas of agenesis. The shape of the skull gives the microcephalic a bird-like appearance. In addition he is usually of small stature. The brain has fewer cells than normal, but shows numerous embryonal and heterotopic cells. The majority of microcephalics belong to the idiot and imbecile classes; a few are merely feeble-minded. As a group they are vivacious, restless, affectionate and well behaved.

Mongolian aments are so called because the eye-slits shape obliquely upwards and outwards. The epicanthic fold of skin at the inner canthus is strongly developed. In addition the tongue is large and marked by transverse fissures—the “scrotal tongue”; and the skull is brachycephalic from flattening of the frontal and occipital regions. The first dentition is delayed; the teeth are small and decay early. The nose is short, the hands and feet broad, the thumbs and little fingers shorter than normal, while the latter are slightly concave towards the ring fingers. The palms often possess only a transverse furrow—the so-called “simian line.” The ligaments are lax, so that the joints can be hyperextended. Congenital abnormalities of all kinds, and especially congenital heart disease, are common.

Mentally the majority are of imbecile grade. Many are feeble-minded, and a few are idiots. They are placid, given to grimacing and mimicking. They often show a good appreciation of rhythm and a pleasure in music. The cause of mongolism is still in dispute. The one factor that is definitely correlated is maternal age—mongols are born mainly to elderly mothers.

Sclerotic Amentia. Amentia is dependent in a small proportion of the cases upon neuroglial lesions either in a diffuse or in a circumscribed (nodular or tuberous) form. In both instances the picture of mental defect is complicated by various paralyses, by tremors, and, especially in the tuberous form, by convulsions. In a few cases of tuberous sclerosis, adenoma sebaceum and tumours of various internal organs have also been present. To such a combination of lesions the term “epiloia” has been given. In the hypertrophic diffuse form of sclerosis headaches are a prominent symptom.

Sense Deprivation and Mental Defect. It is now realised that the mental defect commonly associated with a lesion of one of the organs of special sense is more apparent than real, and is dependent not on innate deficiency, but lack of education through the missing organ. Recent special tests of the intelligence of children completely deaf from an early age have shown that they are no less intelligent on the average than the normal child.

Idiots savants are persons who, although suffering from a general mental deficiency, yet exhibit an unusual aptitude in one direction. For example, some imbeciles and feeble-minded persons have a phenomenal memory.

Incidental Psychoses and Psychoneuroses complicating Mental Deficiency. Mentally defective persons, even more than ordinary people, are liable to develop mental illness of some kind or another in face of difficulties. But just as they more easily develop incidental psychoses or psychoneuroses, so they recover, on the whole, more readily. The emotional disturbance of the psychosis may however leave the patient even less socially adequate than before, so that for example a defective who before the onset of a schizophrenic episode was able to live in the outside world may, in spite of the subsidence of schizophrenic symptoms, have to remain permanently thereafter in an institution. Hysterical manifestations in defectives are apt to be more gross than in individuals of normal intelligence. The patient has visions and hears voices with great readiness, and the hallucinations have a childlike simplicity; while paralysis of entire limbs is preferred to the tremor and aches and pains so common in the average hysteric.

Treatment of Mental Defect. The problem of mental defect arises principally in three spheres: of education, social control, and occupation. Any child who is a year or more behind the average intellectual development of his age (the “dull and backward” group) is best taught in a special class. When the defect amounts to three years or more, a special school is desirable, with special methods of teaching and special attention to simple handicrafts, and only as much instruction of the scholastic kind as the child can assimilate. Home control revolves round two factors in the child: his intellectual and his temperamental status. Often the parents are annoyed by his apparent stupidity,

while his brothers and sisters tease him. They must be taught to make allowances. Temperamental difficulties may be controlled by wise parents, but if, as too often happens, one or both of the latter are themselves defective, a foster home may be necessary. Legal provision is made for placing defectives under "guardianship" or in approved homes.

Where the defect reaches an intensity which makes these methods inapplicable, resort must be made to institutional care after certification as detailed in the section on legal aspects.

The question of occupation after leaving school is very important. A suitable choice may produce a useful citizen; an unsuitable choice may result in, first, frequent change of job, and, later, chronic unemployment and sometimes also delinquency or crime. The choice has to be made on the basis of a knowledge of the child's school achievements, supplemented, if necessary, by special tests of industrial aptitude.

LEGAL RELATIONSHIPS

LUNACY CERTIFICATION

Certification that a person is a "lunatic" or "of unsound mind" involves, besides the actual problem of certification, the question of the legal responsibility of a medical man for any certificate he may write. Certification is fundamentally a legal proceeding. It is not merely a step towards treatment, but a certified lunatic is *ipso facto* deprived of some of his civil rights, including his liberty. Furthermore, it is necessary to remember that not only are there direct legal consequences of certification, but there may be indirect civil consequences as well; for example, if a business man has once been certified, and knowledge of the fact comes to his professional colleagues, he may find himself deprived, if he recovers, of his right to serve on a board of directors or to hold some similar position of trust. Accordingly, in certifying a patient the following points must be carefully considered: (a) whether certification of the patient in question is medically desirable; (b) whether it is legally possible; and (c) whether, if (a) and (b) are satisfied, certification will grievously handicap him in his business after his recovery. It should be observed that the practitioner certifies not only that the patient is of unsound mind, but "a proper person to be detained under care and treatment." The reasons for certifying that the patient is such a person were detailed by Sir Claud Schuster, Permanent Secretary to the Lord Chancellor, in his evidence before the recent Royal Commission, as follows: (1) to protect the public from injury; (2) to protect the patient from self-injury; (3) to give treatment with a view to cure or amelioration which cannot otherwise be given; (4) to protect the patient from injury due to want of care.

Any disorder of conduct resulting from disorder of mind, which disables the patient socially to such an extent that he is incapable of looking after himself or his affairs, is sufficient ground for certification. But it is to be noted that there must be disorder of mind, and there must be disorder of conduct involving either conflict with society or unnecessary loss to himself, or there must be disorder involving neglect of his personal health and safety. Mere disorder of mind, if the conduct remains socially normal, is not a ground for certification. Thus a patient who firmly believed over a period of twelve years that he was in daily communication with the rulers of this country and the commanders of its armies, but who carried on a successful business and lived a happy family life the while, did not become certifiable till, as the result of business reverses, he became depressed and attempted suicide by thrusting a hat-pin twice into his abdomen. In other words, the mere presence of delusional beliefs does not give ground for certification. On the other hand, the absence of demonstrable abnormal mental trends does not make certification impossible, for abnormality of conduct alone

can form a valid basis. A patient who, in the absence of physical reasons, becomes inactive, refusing to eat and to attend to the calls of nature, may have to be dealt with by certification to enable adequate methods of feeding to be instituted.

The patients most difficult to certify are (1) those who are antagonistic and have sufficient control and insight not to give themselves away in the presence of the examiner; this group includes paranoid states especially; (2) those who have a disorder of conduct only exhibited in special circumstances or in relation to certain persons, and who show little or no demonstrable mental defect or disease apart from such conduct, and who deny the conduct; such are certain chronic alcoholics who shamefully misuse their wives and families; (3) those with intermittent or episodic attacks of mental illness, *e.g.* epileptics and alcoholics who are still sufficiently well in the interval not to show any disorder of a degree that would carry conviction to the lay mind (which for these purposes is also the legal mind); it is, however, not justifiable to certify a chronic alcoholic patient during an attack of delirium tremens, if he is not certifiable in the interval; (4) the mildly excited patient, who may be extravagant and lacking in finer discrimination and may play havoc with his business in consequence, but who in an interview is suave and plausible when questioned about his business transactions.

In any case a mentally sick patient should be certified only for his own safety and protection or for the protection of society, and only where no other method medically as efficacious presents itself. Such another method may fortunately be found in the provisions that are made for voluntary patients in mental hospitals. This method requires that the patient himself shall sign a letter in which he states that he wishes to place himself under care and treatment in a certain hospital which he names. No other formality is necessary. In the case of patients under sixteen, there is a special form which is signed, not by the patient, but by his parent or guardian, to which is appended a recommendation by a medical practitioner. This, whenever the patient can be persuaded to sign, is the method of choice. It has none of the drawbacks of certification. It has, however, some disadvantages of its own. (1) It is precisely the patient most difficult to certify who cannot be persuaded to sign a voluntary document—the paranoid, the chronic alcoholic and the hypomanic. (2) A patient placed in hospital on a voluntary basis is permitted to leave on seventy-two hours' notice. This can be very inconvenient, harmful and even dangerous in a patient who, for example, is suicidal. In such an event, the only procedure that is fair to the patient is to have him certified, although no one would like to persuade a patient to enter a hospital as a voluntary boarder and then to detain him by certification if he insists on leaving. The better method is to discharge the patient to the care of friends before certifying. In England, by the Mental Treatment Act of 1930, the voluntary method now applies to both private and rate-aided patients; the latter cannot afford to pay anything at all. The lowest rate for board, lodging and medical attendance for a private patient in a private mental hospital is usually about £3 3s. a week; but in several public (*i.e.* rate-supported) mental hospitals, in and outside London, voluntary boarders are admitted as private patients for £2 2s. a week.

The legal sanction to certify a patient as of unsound mind is given in the Lunacy Act, 1890. There are various forms of procedure in committing a patient to a mental hospital, designed to meet different cases. Method (1): by *Reception Order on Petition*. This applies only to private patients who have been living in their family or with their friends. For rate-aided patients the method (2) is by *Summary Reception Order*. This second method is also applicable to private patients who (a) are not under proper care and control (b) are cruelly treated or neglected by their relatives, or (c) are wandering at large. Method (3) is by *Urgency Order*, and method (4) by *Inquisition*. The latter is a special and

elaborate method rarely used nowadays, and reserved for instances where a large estate is involved (13).

Method (1). For the complete legal process of certification by *Reception Order on Petition* five documents are required: (1) the petition of the nearest relation or the nearest available relation or, failing them, of any other person; but failing the nearest relation, the reason why the latter is not the petitioner must be stated; (2) a statement of particulars, consisting in answers to a series of printed questions; (3) and (4) two medical certificates, described below; (5) the reception order, signed by the appropriate judicial authority, authorising the patient's reception in a recognised mental hospital or home.

Method (2). In procedure by *Summary Reception Order* the necessary documents are similar, but there is no form of petition, since the relations or friends are not available. The statement of particulars is signed by the civil authority, e.g. any constable, relieving officer, or overseer of the parish in which the alleged lunatic is found. The form of the medical certificates is in all cases the same as in method (1). Two certificates are required for private patients, and one certificate for a rate-aided patient.

Method (3), by *Urgency Order*, is intended to be used only if it is essential that the patient shall be moved to hospital at once. Only one medical certificate is required, together with an order, signed by the nearest relative, or if the nearest relative is not available by some responsible person, the reason for the absence of the nearest relative's signature preferably being stated. A statement of particulars must be enclosed, and signed by the person signing the Order. If the person signing the Order is not the same as the signatory of the statement, the reason must be stated. An Urgency Order remains in force for only seven days, by which time, if the patient has not recovered, it must be replaced by a certificate under methods (1) or (2). The practitioner signing the certificate to accompany the Order must have seen the patient within two clear days before signing, or preferably (according to comments in the recent case of *Hume-Spry v. Smith and Another*, *Times*, 1927) on the same day. Similarly the relation or other person signing the Order itself must have seen the patient within a similar interval.

The Mental Treatment (England) Act of 1930 introduced a further method of placing a mentally ill person in a recognised hospital or home, without actual certification. This is the method of Temporary Recommendation, and applies only to the so-called non-volitional cases, i.e. the patient who is judged incapable of either giving or withholding his consent to be placed in hospital. Strictly interpreted the operation of the section is confined to delirious or stuporous patients, but judging from the official attitude of encouragement revealed in the Board of Control's Reports, some latitude is allowed in the clinical interpretation, so that, e.g. manic excitements not of delirious intensity may be included. The method requires that a request be signed by a relative in the case of a private patient, or by the civil authority (Public Assistance Officer) in the case of a rate-aided patient, and that two medical recommendations should be signed, one by a medical man specially recognised by the Board of Control for the purpose.

Medical Certificates. One of the certificates for the Reception Order on Petition must be signed by the usual medical attendant of the patient, unless some valid reason for being unable to obtain such certificate is mentioned in the petition, when both certificates may be given by independent medical practitioners. The two certifying practitioners must make their examinations separately. Mr. Justice Hawkins in *Weldon v. Semple* said: "The statute requires separate examinations by the medical men, and here they both go together—as gross an evasion of the Act as could be conceived. . . . Anything more calculated to excite suspicion could not be supposed than both the doctors meeting and going together." But where one of the certifying doctors has not previously seen the patient—as is usually the case, since both cannot be the

patient's "usual medical attendant"—it is obvious that he must be made acquainted with the previous and the present conditions before he proceeds to his examination. It is therefore suggested that to conform to the law in the letter as well as in the spirit, a certain interval, say of a day or at least of several hours, should be allowed to elapse between the visit of the consultant and the visit for purposes of certification of the usual medical attendant.

There are certain *statutory prohibitions* which should be known to the medical man signing a certificate—prohibitions which are designed to eliminate the entrance of self-interest into the examination. The medical certificates must not be signed by any of the following persons: (1) a practitioner related by blood or business to the other certifying practitioner—father or father-in-law, mother or mother-in-law, son or son-in-law, brother or brother-in-law, sister or sister-in-law, partner or assistant; (2) a practitioner who is at the same time either the petitioner himself or the superintendent, proprietor or medical attendant of the asylum, hospital or house to which the patient is sent; (3) a practitioner interested in the payments on account of the patient; (4) the husband already named, or wife, father or father-in-law, etc., of any of the persons.

The Medical Examination. The examination with a view to certification must be made separately, as stated above. A physician is sometimes asked by relatives labouring under a mistaken idea of tactfulness to see the patient under a false guise, and not as a medical man at all. He should never be persuaded to do this. It is essential to be quite frank with the patient, and if he asks point-blank whether the intention is to certify him, the practitioner should state that he has come to see the patient about the state of his health, especially his mental health; that there is no intention of certifying him if it can possibly be avoided; and that in any case certification is only performed by medical men when it is definitely necessary for purposes of treatment.

The medical practitioner should always *take notes* of the interview, either while it is going on, or, if that is impossible on account of the patient's suspicion or of his conduct, such as the rapid flight of his ideas, he should make notes immediately after leaving the patient. These notes should contain all the relevant facts that have been elicited. Some verbatim samples of significant portions of his stream of talk are invaluable. The necessity for taking notes—and preserving them—of every case which one certifies seems to be shown very clearly by the strictures of the Judge upon Dr. Fisher in the recent case of *Harnett v. Fisher*. Dr. Fisher certified Mr. Harnett to be insane in 1912, and Mr. Harnett brought an action for negligence resulting in wrongous certification in 1926, fourteen years later. The Judge asked, "Tell us one single question you asked him." Dr. Fisher replied, "I must have asked him something, but I do not remember what the phrases were." The Judge said: "I should have thought you would have told us the questions you asked him," and commented, "He says he put such small questions, he cannot tell what they were."

The examination itself should be conducted as any other mental examination is conducted, in a systematic fashion, taking each topic in turn as far as possible. A careful physical examination should always be included (*cf.* case of *Hume-Spry*). It is necessary also to inquire about the mental condition of the patient before the onset of his illness. Valuable confirmatory evidence may be obtained in this way, and, on the other hand, rash conclusions may be avoided. It has been pointed out that great religious activity may be a fairly normal characteristic of one individual, *i.e.* of some one who has previously been of a religious turn of mind, but totally foreign to another individual's mentality and so a symptom of illness.

There are certain points which are specially telling in a certificate, and which should be stated if they are observed. Strangeness of conduct is one of these, *e.g.* mutism and resistiveness. The presence of morbid ideas is another, especially if they have developed to the extent of being delusions. But it is insufficient

to state in the certificate that the patient has delusions. The delusions, or some of them, must be specified in detail, and further (what is equally important) the medical practitioner must be reasonably certain that they are in fact delusions. Thus a man may be jealous of his wife and say that she is having an affair with another man. This may be true, and it is very difficult to disprove, so that the physician has only the presumption of its falsity to go on. A patient said that every one was looking at him and talking about him in the workshop in which he was employed. This was true, and not a delusion. His erratic conduct had drawn their attention on numerous occasions. In reporting a delusional idea, therefore, it is necessary for the practitioner to add some such phrase as "which I believe to be false," or "which I know to be false." Hallucinations are useful evidence for a certificate, being convincing to the layman. It is, however, not infrequently impossible to state their content, and their presence is often a matter of more or less expert inference from the patient's behaviour. Nevertheless, as they are very generally accepted evidence of insanity, the evidence of their presence should be included in the certificate.

Neither delusions nor hallucinations may be present, and the affective condition alone may be sufficient for certification, provided it is abnormal enough to influence behaviour in the direction either of inactivity, of agitation, or of attempts at suicide. Merely the expression of suicidal ideas, if in a setting of considerable depression, is sufficient for a certificate to be written, since in such a setting they are very apt to be carried out. Suicidal determination, in the absence of demonstrable mental disorder, can apparently only be dealt with in law by the police if ordinary persuasion fails. Defects of memory, of orientation, and of comprehension are very useful corroborative evidence. They are not usually considered sufficient in themselves to establish the validity of a certificate, but they are not infrequently made to serve in the case of old people who cannot be looked after at home and who require special care on account of their increasing mental inadequacy.

It is very unwise to put a diagnosis in a certificate. It adds nothing to the facts, and it may be wrong (*cf. De Freville v. Dill, Times, May 19th, 1927*, where the certifying practitioner wrote that the patient was suffering from acute mania, and where it was subsequently proved that within twenty-four hours of the certificate being written to that effect the patient was perfectly normal).

The second division of the certificate is for "facts communicated by others." A valid certificate can never be made on these facts alone, and this section may be left blank entirely. But where the facts observed by the practitioner himself are not very conclusive, the "facts observed by others" may be of considerable value. The full name, address and occupation of the informants must be given. It is probably better to make a rule of placing information in this section whenever it is available. It helps to show "reasonable cause." The patient should evidently be questioned on these facts alleged by others. In the *Harnett v. Fisher* action, already referred to, the judge asked Dr. Fisher, "Why did you not take the trouble to ask him about matters the brother had spoken of—whether they were correct or not? You answered he was incapable of telling you anything because he could not speak. How could he tell you anything unless you asked him?" Also in the case of *Hume-Spry v. Smith and Another* the plaintiff complained that in certifying him the defendants relied on his having fixed delusions that his wife had committed misconduct, and on statements that he had tried to murder his wife and to commit suicide. The plaintiff contended that the infidelity was a fact, and that the allegations about himself were false. The defendants had to admit that they had made no attempt to discover whether the patient's statements were true and that they had omitted to question the patient on the topic of his alleged attempts at murder and suicide. Counsel for plaintiff asked, "How can you determine whether a man is wrongly charged with using threats unless you ask him about them?" (*Times, March 12th, 1927*).

Finally, the practitioner signing a certificate of unsoundness of mind must be in actual practice as well as being registered. The date of examination stated in the certificates (not only the date given at the foot) must be within seven clear days of the petition. All blanks on the certificate must be filled in.

Protection of Practitioners. Since certification deprives the person certified of his civil rights, it is an act which involves great responsibility and should never be undertaken without the most careful consideration. It is a step also which may have serious legal complications, for the person certified may, in indignation at the deprivation of his liberty, ask for a trial by jury as to his alleged insanity. Furthermore, when a person who has been certified recovers sufficiently to be set at large, he may take action for "wrongous" certification. Lunacy certification involves apparently greater risks than most other forms of medico-legal work. There is even a small class of patients in whom litigiousness is the main symptom—namely, the so-called "litigious paranoiacs." Further, patients recovered sufficiently to be discharged from certification have often incompletely recovered and may continue to have delusions which may very well be directed towards the medical men who were the apparent "*agents provocateurs*" of the detention. It would therefore seem *a priori* probable that a medical man certifying a patient undergoes a peculiar risk of actions for damages. This has been a very prevalent impression, but, notwithstanding some recent alarms, it is not the case in practice that the certifying practitioner is peculiarly liable to actions at law. Only one action for wrongous certification has ever been brought in Scotland, and "that action should never have been brought" (Robertson). The practitioner is now more adequately protected by the Mental Treatment Act of 1930. By Section 16 of this Act, it is necessary for the complainant to lay a petition before a Judge in Chambers, and to show that the certifying practitioners acted in bad faith and without reasonable care. It is still very desirable that every medical practitioner should join a medical insurance society. Otherwise he may find himself involved in litigation which is ruinous to him as a private individual depending on his own financial resources.

When there is any doubt in the practitioner's mind as to the desirability of certification, a second visit to the patient may be helpful, and certainly will help to forestall any allegation of want of reasonable care.

On the other hand, refusal to certify may also carry legal responsibility for the practitioner. This point is not legally settled. Mr. Justice McCardie suggested that, while a doctor might owe such a patient care about certification, he might not be liable to the patient for negligence if he refused to certify a person actually of unsound mind who afterwards injured himself (*De Freville v. Dill*; editorial, *Times*, July 8th, 1927).

Appointment of Receiver. When a person has been certified as of unsound mind, and has property or a business which must be administered, and when it is considered that his mental disorder makes him incapable of business transactions, application is made to the Judge in Lunacy by the petitioner for the appointment of a receiver. The latter may be the nearest relation or a solicitor, or other person elected by the Judge. When the patient is decertified he has to make application to the Judge for the termination of the receivership.

When a person who is not actually certified is considered to be incapable of managing his affairs, and when it is necessary that some one should be appointed to manage them, either the patient may grant a power of attorney to some person approved of by him or, where this is inadvisable or not permitted by the patient, the usual medical attendant of the patient may, at the request of the patient's representatives, make an affidavit that the patient is, "by reason of mental infirmity arising from disease or age," incapable of managing his affairs (sect. 116 of the Lunacy Act of 1890). A receiver is appointed accordingly by the Judge in Lunacy after he has satisfied himself of the necessity for the step.

MENTAL DEFICIENCY

Mental defectives are dealt with under the Mental Deficiency (England) Acts of 1913 and 1927.

Certification of a person as mentally defective under the Acts is carried out as follows: (1) If the patient is an idiot or imbecile of any age, the parent or guardian signs a statement of particulars. In addition, two medical certificates are required, one preferably by the usual medical attendant and the other by a medical practitioner specially approved for the purpose by the Board of Control. (2) If the patient is feeble-minded or a moral imbecile and is under the age of twenty-one, the procedure is as with idiots and imbeciles, but a certificate from a judicial authority is required in addition. (3) If he is a defective of any class or age, under *special circumstances*, as (a) neglected, abandoned, without visible means of support, or cruelly treated; or (b) found guilty of any criminal offence, or ordered or liable to be ordered to be sent to a certified industrial school; or (c) undergoing imprisonment or detention, or in an institution for lunatics; or (d) is a habitual drunkard (and some other provisoes), certification is carried out as follows: (i.) by petition with two medical certificates, one of which must be by a medical man specially approved by the local authority or Board, with a statement of particulars, and a statutory declaration by the petitioner, and a judicial order by a county court judge, a magistrate (police or stipendiary), or a justice of the peace specially appointed; (ii.) by order of the court, on conviction, or on a child being found liable to be sent to an industrial school; (iii.) by order of the Home Secretary (on imprisonment, detention in a reformatory or in a criminal lunatic asylum), with two medical certificates. In certification for this class of patient, the precautions and forms to be observed are very similar to those in lunacy certification, but the class to which the defective belongs must also be stated. General statements, such as "he is lacking in judgment," must be supplemented by the mention of actions or statements of the patient himself.

TESTAMENTARY CAPACITY

The practitioner is sometimes asked to adjudicate on a patient's mental capacity to make a will. The tests he has to apply are not identical with those required in matters of certification. All that is needed for testamentary ability is that the testator "shall understand the extent of the property of which he is disposing; shall be able to comprehend and appreciate the claims to which he shall give effect"; and shall not have such a disorder of mind that his sense of right or his affections are perverted—so that, for example, delusions influence him in disposing of his property; or a gross defect of memory prevents him from exercising his natural faculties. Hence a patient may be certifiably insane (from the point of view of his own safety), yet be capable of executing a valid will. On the other hand, he may suffer from such a disorder of mind that he can live at home, yet be incapable of making a will. This occurs principally in persons suffering from senile cortical deterioration, in whose case there is a gross defect of memory and comprehension.

CRIMINAL RESPONSIBILITY

The problem of criminal responsibility is the most debated of those concerning the social relations of psychological medicine. Medicine and the law have a difficulty in seeing eye to eye in regard to it. This is not surprising, and is usually held to arise from the divergence in social outlook of the lawyer from that of the medical man. The former is concerned for the safety of society, the latter for the welfare of the individual. "When I am tempted to pity the criminal, I remember also that there is a pity that is due to my country" (Sir Matthew Hale). But this is not the principal point. The difference lies rather in the

divergence of the legal from the medical concept of mind and mental disorder. The legal concept is of mind dominated by reason and freewill; the medical concept is of functions actuated by emotion and determined by intrinsic factors. In the legal mind everything is consciously known; in the medical mind much in unconscious and unknown. Hence come certain differences in medical and legal criteria of responsibility (5).

The plea of insanity (in bar of trial or in bar of sentence) is confined almost exclusively to murder trials. This does not mean that murder is almost the only criminal act which mentally ill persons commit. Arson, sexual offences, larceny, and so on are commoner among them than murder. But the defence of insanity in these conditions, if successful, leads only to compulsory detention in an asylum; and the net result is not profitable for the patient, since he could have gained his liberty just as soon if he had not been found a lunatic by the court. In capital crimes, on the other hand, a successful plea of insanity saves the patient from hanging. The law presumes that every person is innocent until he is proved guilty, and likewise that every person is sane until he is proved insane, in both cases to the satisfaction of the jury. The burden of proof of insanity rests therefore upon the defence. For proof of insanity there must be fulfilled the following conditions according to the current law of England.

McNaghten Rules. The accused must be proved at the time the action was committed, first, to have had disease of the mind; second, not to have known the nature and quality of his act, or (not "and"), third, not to have known that the act was wrong. These conditions are not actually embodied in a statute, but they are the substance of the answers in the McNaghten case (1843), and they have been the basis of all legal decisions as to criminal responsibility since that date. They refer to the time of the act of which the person is accused. They refer specifically to that act and the knowledge of it, and not to crime in general. The knowledge required is not of legal right or wrong: the accused person is not assumed to know any more of legal right and wrong than is the common property of the community. It is in effect the capacity to determine the moral quality of the act that determines responsibility. The McNaghten Rules partake of the medically out-of-date doctrine of the mental faculties and its corollary, partial insanity, the mind being regarded as divided up into a series of independent compartments, the cognitive faculty being one of the large subdivisions. Medicine has come to recognise that the mind is a whole, one and indivisible. There is no mental disorder, however partial in appearance, that does not have its reverberations throughout the rest of the affected mind. Consequently the purely intellectual criterion of responsibility falls to the ground, for the intellect as intellect may be unimpaired, but an emotional disturbance will alter or impede or nullify its effect on conduct. Conversely, intellectual defect means deficient emotional control. The influence of the doctrine of partial insanity on the judges who propounded the McNaghten Rules is shown in their reply to the fourth question put to them: "If a person under an insane delusion as to existing facts commits an offence in consequence thereof, is he to be executed?" "The answer," said the judges, "must, of course, depend on the nature of the delusion; but making the same assumption as we did before—namely, that he labours under such partial delusion only, and is not in other respects insane—we think he must be considered in the same situation as to responsibility, as if the facts with respect to which the delusion exists were real. For example, if, under the influence of his delusion, he supposes another man to be in the act of attempting to take his life, and he kills that man, as he supposes, in self-defence, he would be exempt from punishment. If his delusion was that the deceased had inflicted a serious injury to his character and fortune, and he killed him in revenge for such supposed injury, he would be liable to punishment." The insane person may then kill a man with impunity if he believes that he is doing it in self-defence, while he is punished by death for a homicidal act which results from the belief

that the victim was reading his thoughts or tampering with his genitals. No account is taken of anything but apparently intellectual operations and their influence on conduct. No apparent allowance is made for such well-known phenomena as post-hypnotic and epileptic automatisms.

The practical issue is this: that, whereas it is nominally required in the trial of a person pleading insanity in extenuation of a crime that evidence be taken bearing both on his general state of mind at the time of commission of the crime and on his particular knowledge of the moral nature of the act, it is to the latter, the knowledge of the criminal act, that attention is principally or entirely devoted by the court. Consequently it not infrequently happens that a person who, from a general survey of his mental state, was undoubtedly insane at the time, is found sane in respect of the commission of one particular act, the criminal one. "It follows that a man can legally be hanged for murder and yet be regarded by the same court as unfit to take care of himself or his property" (Singer and Krohn). Fortunately for the insane criminal under sentence of death, there is a proviso in the Criminal Lunatics Act, 1884 (sect. 2, sub-sect. 4), that when the Secretary of State is informed by any means that there is reason to believe that a person under sentence of death is insane he shall appoint two or more legally qualified practitioners to examine such prisoner and to inquire as to his insanity. If the medical men or a majority of them find he is insane, the Secretary of State may, if he thinks fit, direct the prisoner's removal to an asylum (for criminal lunatics). In the end then the prisoner may be judged at his trial insane, but worthy of punishment, only to be exempted from it while awaiting execution of his sentence.

The law has taken some cognisance of the inconsistencies revealed in these ways by the exercise of wide powers of discretion by the judge in his instructions to the jury, and, more recently, by the appointment of a special committee under Justice Atkin (following the trial of Ronald True). The Atkin Committee made the following recommendation: "It should be recognised that a person charged criminally with an offence is irresponsible for his act when the act is committed under an impulse which the prisoner was by mental disease in substance deprived of any power to resist."

This recommendation, if adopted, would avoid certain difficulties arising out of the unqualified application of the McNaghten Rules. But it does not remove or supplant these rules, and consequently does not correct the antiquated theory of mind and mental disorder which they represent. The position of medical men who appear as witnesses in trials of criminal responsibility where a plea of insanity is put forward is beset with difficulties and disadvantages. First, the medical witness (an expert, and not an ordinary witness to fact) appears on one or other side of a case in which he is summoned. He is therefore, in the eyes of the court, to that extent biassed. He is obliged to gather his evidence partly retrospectively from the accounts of biassed persons (the patient and his friends). His personal direct observations of the prisoner's mental condition are made under the least favourable conditions—the accused person is in prison, and the time and opportunity for observation is limited by the circumstances of incarceration and of the fixing of an early date for the trial. In court he is asked to direct his attention less to what his training best enables him to judge, namely, the general mental state of the prisoner, and more to the much more difficult question of responsibility for a particular act, which is a matter of opinion.

The first of these difficulties the practitioner can do something in himself to mitigate. When asked to see a prisoner on behalf of one or the other side, he should reply that he will see him and examine him, that he will submit his report in accordance with the facts he finds, and that if, on the basis of his report, the legal advisers who made the request desire him to appear, he will do so.

To meet the other disadvantages, suggestions have been made, that to avoid

medical witnesses appearing on opposite sides, a panel of impartial experts should be appointed who will make a combined report to the court. But this does not yet occur in this country. To give time for sufficient examination, provision is made in certain countries for transfer of the patient to a psychopathic hospital for observation for a time. As an answer to the final objection—that medical witnesses are asked to testify to presence or absence of specific responsibility—it has been urged that responsibility is for the jury to decide. The British Medico-Psychological Association in a recent recommendation suggested that, in addition to the question laid down in the McNaghten Rules, the jury should be asked whether they considered the prisoner was insane at the time, and whether his act was related to his insanity.

DISEASES OF THE SKIN

(DERMATOSES)

It is not possible in a general text-book of medicine to present a complete review of the diseases of the skin, and in the following section much of importance has been omitted. It has been thought advisable, for example, to refer the reader to text-books of dermatology and surgery for descriptions of many tumours of the skin, both innocent and malignant, and no account will be found of the various diseases of the nails or of radiodermatitis. Dermatology has unfortunately in the past been regarded as a subject apart, and has been both neglected by the general physician and misunderstood by professed dermatologists. In reality it is clinically one of the most important of the special branches of medicine, since the skin is the mirror in which the state of the general health can be read, and a knowledge of the ætiology of its commoner disorders provides the key to the proper understanding of the pathology of disease. Of recent years dermatology has become more and more a part of general medicine, and it is as essential nowadays for the physician to acquaint himself with modern dermatological teaching as it is for the dermatologist to keep abreast with the advances made in medical pathology.

The skin is liable to the same pathological conditions as other organs and structures in the body, and the classification of its diseases is based upon these.

Thus there are changes in vascularity, inflammations, new growths, structural changes due to the presence of micro-organisms, such as those of tubercle or leprosy, lesions resulting from the circulation of disease-toxins, such as those of scarlatina and other exanthemata, the invasion of animal and vegetable parasites other than bacteria, hypertrophy and degeneration of the separate structures of the skin, and changes of pigment.

We have to consider also the disorders of certain organs contained in the skin, namely, the hair, the sebaceous glands, and the sweat-glands or coil-glands.

Many disorders of the skin have been already described, as, for instance, the eruptions characteristic of the exanthems, the cutaneous lesions of syphilis, lepra, glanders, actinomycosis, and elephantiasis, and the forms of hæmorrhage known as purpura.

The discrimination of the various diseases is based upon a careful observation of the local changes, or lesions, which take place in the skin, combined with a consideration of their distribution, duration, and associated and antecedent circumstances.

PRIMARY LESIONS

Blebs or Bullæ. Large vesicles, from 5 mm. to an inch or more in diameter. The fluid contents are clear, or slightly turbid, or bloodstained. They are often situated on an inflamed base: they heal by discharge of the contents, and the drying and shedding of the epidermic scale. **Chaps, Rhagades, or Rimæ.** Cracks or fissures through the epidermis, reaching the stratum mucosum or corium beneath, very sore and apt to bleed. **Excoriation.** A patch of skin deprived of the upper layer of the epidermis, and exposing the stratum mucosum. It is of a vivid red colour, and tender to the touch; and it secretes a small amount of serum, which may dry into a crust. **Hæmorrhages.** Cutaneous hæmorrhages

form larger or smaller spots of bright red, dark red, or purple colour: they do not disappear on pressure. As a rule, the blood is gradually absorbed, and the colour fades into brown or brownish-yellow, or becomes successively brown, green, and yellow, in the larger subcutaneous hæmorrhages. A yellowish-brown stain may be left for a long time. The smaller spots are called *petechiæ*, the larger *ecchymoses*; if they form streaks they are called *vibices*. In *capillary ecchymosis* a very fine mottling is produced, which looks like a hyperæmia, until it is found to persist under pressure. Exceptionally the skin involved in hæmorrhage sloughs and leaves an ulcer. **Hyperæmia.** This consists of redness, of varying extent, due to the blood vessels being distended with blood. It may be: (1) an *active hyperæmia* from vasomotor action; (2) an *early inflammatory hyperæmia*, with slight swelling, tenderness, and some indications of pyrexia; or (3) a *venous hyperæmia*, or passive congestion, with a more blue or livid colour than in the other forms. In all cases the redness disappears on pressure, to return when the pressure is removed—quickly in the first two cases, slowly in the last. **Macules.** Small areas of discoloration of the skin, which are unaccompanied by alteration in its surface or consistence. They may arise from a preceding hyperæmia, and then disappear shortly. They are generally more permanent if arising independently. **Nodules.** Solid elevations larger than papules. **Papules.** Small elevations of the skin, solid, or at least not visibly containing fluid. They arise mostly in the cutis, but may be imitated by accumulations of epidermic scales. They may be pointed (acuminate), obtuse, or flat (plane). **Pustules or Pustulæ.** Vesicles or bullæ containing pus. **Scabs or Crusts.** Irregular flat masses of dried serum, pus, or blood, or a mixture of these materials, forming upon and adherent to the raw surface which has secreted them, and frequently the result of a vesicle, pustule, or bulla. **Scales or Squamæ.** Collections of epidermic cells in the form of flakes. Sometimes, as in dandruff, there is a large admixture of the fatty matter of sebum. Scales vary from the small branny particles of measles (furfuraceous) to the large exfoliations seen in exfoliative dermatitis and in some cases of scarlatina, or the thick adherent masses of psoriasis. **Scar or Cicatrix.** The new growth of connective tissue, which results from the healing of sores, involving the papillary layer and deeper corium. When recent, they are pink or bluish in colour. Finally they become dead white, and contract in size. **Scratch Marks.** Linear or, if at the apices of erected follicles, punctate, produced by the nails, and bearing small crusts of blood. Ultimately, if deep enough, they may become linear or fusiform cicatrices. Their direction generally bears a definite relation to the position of one or other hand. **Sore or Ulcer.** A loss of substance involving the whole epidermis and part or the whole of the corium. The base is covered with granulations, and secretes pus. It heals by scarring. **Telangiectases.** Dilated superficial venules of the subpapillary plexus. They are often seen on the malar regions and nose, particularly in rosacea and in those who have been much exposed to cold and sunlight. They are a feature of radiodermatitis and lupus erythematosus. **Vesicles or Vesiculæ.** Small blisters from 1 to 5 mm. in diameter, due to the accumulation of clear fluid under the upper layer of the epidermis. They are frequently inflammatory, seated upon an inflamed base, and contain a yellow albuminous serum. **Wheals or Pomphi or Hives.** A circumscribed œdema of the corium, producing a pale pink or white elevation of the skin.

The following Diseases are caused by Infective Organisms

Diseases caused by ultra-filterable viruses.

It is probable that further research will show that several diseases of the skin of unknown ætiology are caused by a filter-passing virus—pityriasis rosea, for example. At present the following have been proved to be of this nature, namely,

molluscum contagiosum, the common wart, herpes simplex and zoster, and lymphogranuloma inguinale.

MOLLUSCUM CONTAGIOSUM (See Plate 58, D, p. 833)

This name is given to small tumours on the skin, which are from $\frac{1}{10}$ to $\frac{1}{8}$ or $\frac{1}{2}$ inch in diameter, lenticular or hemispherical in shape, occasionally globular or pedunculated, somewhat irregular or nodulated on the surface, and of a yellowish-white colour. In the smaller tumours there is a minute opening in the centre: in the larger there are several; and if the tumour be firmly squeezed, a soft gelatinous mass of degenerated cells exudes from these apertures. Examined under the microscope, this is seen to consist of minute oval glistening bodies, the *molluscum corpuscles* or *bodies*. A vertical section through the tumour shows it to have a structure somewhat like that of a racemose gland. There are lobules separated by fibrous tissue; each lobule has externally a row of columnar cells, within this are more oval epidermic cells, and in the centre of each lobule is a collection of the glistening opaque molluscum bodies. The lobules in the larger tumours do not converge to a central duct or opening, but rather lie side by side, and open separately upon the surface.

The process appears to begin by a conversion of the prickle cells of the rete Malpighi into the molluscum bodies, which are stated to consist of keratin. The adjacent part of the rete enlarges downwards into the corium, and the septa between the apparent lobules are the fibrous remains of the papillæ. There is no necessary connection with sebaceous glands or hair follicles.

The growths are thus really benign epitheliomata, and are of interest in that they are caused by an infecting organism which is so minute that it passes through a Berkefeld filter. It may be inoculated by smearing the cheesy contents of the growth into an abrasion on the skin, or, better, by injecting intracutaneously a sterile saline filtrate, made by grinding up the tumours, removed with a curette, with saline solution, and passing the resultant emulsion through a Berkefeld filter. After an incubation period of from five weeks to six months tiny molluscum growths make their appearance along the site of injection.

Molluscum contagiosum is common in birds, from which it may be communicated to man. It occurs both in children and adults, and the tumours are seen most commonly on the face, the arms or hands, the mammæ of women, and the genitals of men. They are apt to suppurate, and may disappear spontaneously; otherwise they may last indefinitely and multiply by auto-inoculation. Very large numbers may occur on the trunk of persons who take Turkish baths frequently, the infection being acquired from the fingers of a masseur or possibly from bath-gowns.

Treatment. The tumours may be caused to disappear by expressing the contents and applying pure carbolic or iodine to the interior, or "by boring into them with a grooved needle dipped into melted silver nitrate, so that it becomes charged with a sheath of the salt" (Whitfield). A simpler method is to scrape them away with a small curette, and paint the affected surface with weak tincture of iodine.

WARTS

(*Verruca*)

There are several distinct varieties of verruca or wart, of entirely different ætiology. Thus the common wart (*V. vulgaris*) is due to a filter-passing virus, the venereal wart (*V. vel condyloma acuminata*) is probably caused by a spirillum (see p. 888), the seborrhœic wart (*V. seborrhœica*) is possibly a nævoid growth of late development, and the senile wart (*V. vel keratosis senilis*) is a pre-cancerous degeneration of the skin. The last two are often wrongly confused, and neither has any connection with the verruca vulgaris.

Common warts are excrescences from the skin, consisting of hypertrophied papillæ capped with horny epidermis. They vary in shape and size; thus they may be small and flat (*V. plana*), hemispherical, pointed, or pedunculated, and the larger ones may be lobulated or digitate. In colour the flat ones are pale yellow or pinkish, the larger ones darker and of a greyish-brown tint. They occur most commonly on the backs of the hands, on the fingers, and on the face, particularly around the mouth, owing to the tendency of children to bite the original, or "mother-wart," situated on the hand. They also occur on the eyelids and scalp, and on the soles (*V. plantaris*). Large numbers of flat warts are not infrequently met with on the face in children, and sometimes in adults. In the former they are situated chiefly on the forehead, the temples, the cheeks and the chin, and children with seborrhœa and pityriasis of the scalp and face appear to be especially predisposed. In men both flat and pedunculated warts may occur on the beard region, and are spread by the shaving brush and razor. The nail-folds are sometimes involved, the warty growth often extending underneath the nail. *Plantar warts* are very common, and of importance owing to the intense pain they may cause; they are often mistaken for corns. They are usually situated over the heads of the metatarsals or on the heel. They are surrounded by a horny ring, in the centre of which the papillary vegetations can be observed through the transparent corneous layer.

Ætiology. Common warts are seen in children and adolescents more frequently than in adults. They are contagious and auto-inoculable. The infecting organism has been shown to be a filterable virus; plane warts were reproduced by inoculating the juice of crushed common warts, filtered through a Berkefeld filter (1).

Anatomy. There is an enormous hypertrophy and elongation of the papillæ, with thickening of all the epidermal layers. There is no inflammatory change in the dermis.

Treatment. Warts of moderate or large size are easily removed by freezing with a stick of carbon-dioxide snow, after previously softening them with a fomentation. They may also be destroyed with the thermo- or galvano-cautery, by electrolysis, or, if very numerous, by ionisation with magnesium sulphate. Plane warts will often disappear with moderate doses of the X-rays, and also by the repeated application of a 1/1000 solution of biniodide of mercury in 75 per cent. spirit containing 2 per cent. of salicylic acid.

Plantar warts are sometimes difficult to cure, but, as a rule, large doses of X-rays—one-and-a-half to two pastilles,—the surrounding normal skin being carefully protected, are successful. A more certain method is to scrape out the wart from its bed with a Volkmann's spoon under local or general anæsthesia, and to pack the cavity with gauze soaked in tinct. iodi or a 5 per cent. solution of silver nitrate. Internal treatment with magnesium sulphate, the green iodide of mercury, or increasing doses of arsenic is very unreliable. A remarkable fact, since they are caused by a known infective virus, is that warts may sometimes be rapidly cured by suggestion, and this method is currently employed on the Continent and in America. The claims of "wart-charmers" are, indeed, often justified.

HERPES SIMPLEX

Under the term *Herpes* are commonly included two conditions, *H. simplex* and *H. zoster*. The French prefer to restrict it to the former, and to label the latter *Zona*. Unfortunately it has also been applied to a variety of conditions which bear no relationship either to each other or to true herpes, e.g. *H. gestationis* (*Dermatitis herpetiformis* occurring in pregnancy), *H. circinata*, or tonsurans (ringworm), *H. iris* (a variety of erythema multiforme), *H. cretacea* (lupus erythematosus): these terms should be abandoned.

Herpes simplex is an acute eruption consisting of a varying number of vesicles,

grouped together on an erythematous base. There may be one or several such patches. An attack is usually heralded by a feeling of tension, tingling, or burning, in the part to be affected. After a few hours there appears an oedematous patch of erythema, upon which the small clear vesicles rapidly develop: they may be few or very numerous, and, when closely set, often become confluent; occasionally they are hæmorrhagic. Their clear contents become turbid, and then dry into scabs, which fall, leaving a temporary stain, but never a scar. Not infrequently a secondary invasion with a streptococcus takes place, and herpes may be the starting point of an attack of impetigo contagiosa. The adjacent lymphatic glands may be slightly swollen, but not to the extent that obtains in *H. zoster*.

Herpes simplex may occur almost anywhere, but the sites of election are on the face around the lips and nose, and on the genital organs; not infrequently it is also met with on the ears, the nipples, the mucous membrane of the mouth, and on the buttocks. Its tendency to recurrence is notorious, and it usually affects the same region in the person affected. Darier has recorded profuse eruptions on various parts occurring as a sequel to antityphoidal inoculations.

Herpes facialis seu labialis is the commonest variety. It occurs in association with acute infections, such as the ordinary cold, lobar pneumonia, influenza, cerebrospinal meningitis, and malaria. It is extremely rare in encephalitis lethargica and in typhoid fever. Sometimes it accompanies a sharp pyrexial attack with rigor (herpetic fever), and epidemics of this type have been recorded. In many cases, however, one or repeated outbreaks are seen independently of any acute infection.

Herpes genitalis. This is met with in both sexes. In the male, the eruption affects the inner surface of the prepuce, less often on the outside, the glans, the balano-præputial sulcus, the meatus, or even the urethra. In the female, it may occur on any portion of the vulva, and occasionally in the vagina and on the cervix uteri. Acute and profuse attacks of recurrent herpes in women are met with, in which not only the vulva, but also the inner surfaces of the thighs, the mons veneris, the internatal cleft, and the buttocks, are affected. There is fever, swelling of the parts and neighbouring glands, and severe pain and discomfort, which may necessitate confinement to bed. In both sexes the herpetic lesions are transformed into erosions, which may become covered with a diphtheritic-like membrane, or discharge a fœtid muco-purulent liquid. *Herpes genitalis* in this erosive stage is often confounded with soft sore or a primary syphilitic chancre, and it naturally predisposes to such infections in those who expose themselves to the risk. Moreover, it may mask a syphilitic infection until secondary symptoms develop.

Herpes buccalis is usually seen in conjunction with herpes labialis. Like the latter it is often bilateral, and may affect the mucous membrane of the cheeks, the palate, or the tongue. The vesicles are quickly transformed into erosions. Herpes of the pharynx occurs rarely, and is usually accompanied by fever, intense local pain, and swelling of the cervical glands. The eruption also occasionally involves the conjunctiva.

As has been said, herpes simplex is very apt to recur, and the apparent provoking causes differ in different cases. The most frequent is the common cold. Chronic foci of infection are also often predisposing factors—of the teeth, nasopharynx, nasal sinuses, or middle ear, in labial, nasal, or aural herpes; urethritis, prostatitis, metritis, in herpes genitalis. Treatment of such foci may lead to a cessation of the attacks. Apart from infective conditions, however, certain articles of food, *e.g.* cheese, may appear sometimes to be provocative. In women, apart from the outbreak that may follow defloration, recurrent attacks, either on the lips or vulva, may accompany nearly every period. In men, herpes genitalis may constantly follow intercourse with a certain woman. Reflex irritation, *e.g.* from cutting teeth or dental operations, is also apparent in some cases.

Certain varieties of recurrent herpes may be distinguished. In children and adolescents repeated attacks on one or other cheek are not uncommon. In adults the same is true of the buttocks. Less frequent, but of greater interest, is recurrent herpes of the hands and fingers, which simulates *H. zoster*. The lesions arise along the course of a nerve-trunk, and may be accompanied by sensory and vasomotor disturbances, or even by muscular wasting. In a woman under the writer's care the eruption appeared at every period on the middle finger of the right hand.

Ætiology. As a result of recent researches, it is now established that herpes simplex, whatever the provoking cause may be, is due to infection with an ultra-microscopic filtrable virus. Inoculation of the contents of a vesicle of herpes in man into the cornea of a rabbit produces a characteristic keratitis. This keratitis is transmissible from rabbit to rabbit, and in some cases is followed by severe and even fatal encephalitis. It would appear that a large proportion of persons harbour the virus on their mucous membranes, even though they may not suffer from herpes (2). Keratitis and encephalitis have been produced in rabbits by inoculating the saliva of herpetic and even non-herpetic subjects. Although a mild disease in man, attacks of herpes may be accompanied by lymphocytosis in the cerebrospinal fluid. The question as to the identity of the virus of herpes with that of encephalitis lethargica is still *sub judice*.

Morbid Anatomy. The vesicles are formed in the deeper portion of the rete malpighii by necrosis of the prickle cells, without the "ballooning" that is seen in *H. zoster*, and intercellular oedema. In the corium there is vascular dilatation with oedema, and infiltration with polymorphonuclear leucocytes, which invade the cavities of the vesicles, connective-tissue cells, and a few mast-cells.

Treatment. The early lesions may to some extent be aborted by frequent sponging with alcohol or eau-de-Cologne, followed by the application of a simple dusting-powder or calamine lotion. Ointments should be avoided. In cases of recurrent herpes the predisposing factor or factors must be determined if possible, and dealt with. Radiotherapy, and autohæmotherapy, or other methods of desensitisation, are sometimes partially successful in preventing these recurrent attacks. Recently, varying success has been achieved by subcutaneous injections either of vaccinia virus (calf-lymph diluted 1 in 10), or of an emulsion of the herpetic virus in doses gradually increasing from 0.1 to 1 c.c. at weekly intervals (3).

HERPES ZOSTER (See Plate 61, A, p. 922)

(Zona, Shingles)

This is an eruption of vesicles, arranged in groups, which generally correspond in position to the distribution of a cutaneous nerve. The name zona, or girdle, is taken from the most common or intercostal variety, in which the groups of vesicles extend from the spine round one-half of the body to the middle line in front. The eruption is preceded sometimes by pain, tingling, or smarting, and it may be a little malaise or slight pyrexia; then appear groups of closely set papules, forming red patches, 1 or 2 inches in diameter; and upon these the vesicles quickly arise, with thin walls, clear contents, not very tense, and, when numerous, acquiring a polygonal form from mutual compression. The patches do not all appear simultaneously—for instance, one may form first near the spine, then later one in the axilla, and later again one near the sternum; some patches also—that is, the later ones—may fail to produce any vesicles, the process, as it were, subsiding early or aborting. After a time the contents of the vesicles become opaque or milky, and the vesicle dries into a scab which drops off, leaving a red stain. The milkiness may amount to the formation of pus, and the superficial layer of the skin may be destroyed, so that scars result. Scars may form in each group, but not from every vesicle of a group. Quite rarely extensive sloughing of the skin takes place, leaving deep ulcers, which heal

slowly. Although the patches are obviously related to nerves, on the trunk they form a band from 2 to 4 inches broad, the direction of which is more horizontal than the true course of the ribs ; and the vesicles may transgress the middle line both in front and behind. Occasionally vesicles occur, even abundantly, in parts of the body remote from the nerves primarily concerned (*aberrant vesicles*, or *generalised herpes*).

H. frontalis occupies the area of the supraorbital nerve on the forehead, scalp, upper eyelid, and side of the nose. Herpes of the ear and neighbouring parts may arise from implication of the sensory branches of the fifth nerve, of the facial (*nervus intermedius*) and of the ninth and tenth nerves and their corresponding ganglia. *H. cervicalis* lies over the neck, clavicle, and deltoid ; *H. brachialis* follows the course of the nerves of the arm ; and other similar groupings on the abdomen, thigh, and leg are occasionally seen. An intercostal zona may be accompanied by herpes of the inner side of the arm (intercosto-humeral nerve), or a gluteal by an anterior crural, representing posterior and anterior branches of the lumbar nerves. The eruption is nearly always unilateral, and its bilateral occurrence has very rarely been recorded. An important feature of *Herpes zoster* is that the lymphatic glands corresponding to the affected area are enlarged and tender even before the eruption appears.

The duration of the eruption is from four to ten days, but the disease does not always end here. Especially in old people, neuralgic pain in the course of the affected nerve may continue for months or years, and be a source of serious trouble ; and in a few cases motor nerve fibres are involved as well as the sensory, and paresis of the corresponding muscles has been observed, most often in those supplied by the facial, sometimes in those supplied by the third, fifth or sixth cranial nerves, and by the nerves to the deltoid and abdominal muscles. Frontal herpes may be accompanied or followed by conjunctivitis, ulceration of the cornea, or iritis.

Ætiology. The eruption occurs about equally in the two sexes, and, although very rare in infancy, is seen almost at any age. There would seem to be a seasonal incidence to some extent, more cases being met with in spring and autumn than at other times. There is no doubt that in some instances it is contagious, but less so than varicella. Accumulated clinical and pathological observations suggest that the essential lesion in *H. zoster* is involvement of the spinal posterior root, the Gasserian, or geniculate ganglia, with degenerative changes in the posterior roots, the posterior columns of the cord, and the peripheral nerves ; such involvement may be due to a variety of causes, which may be tentatively classified as follows :—

(a) The relationship of zoster to varicella is no longer in doubt. Suggested first by Bokay in 1892, and insisted on by Le Feuvre and others, it has been confirmed by numerous observations all over the world. The evidence in its favour may thus be summarised : (1) An attack of zoster may be followed by varicella. In a case observed by the writer, that of an elderly man who had not previously had chicken-pox, a typical outbreak of zoster on the trunk was followed about a week later by a generalised eruption of varicella ; at the beginning of his attack of zoster he visited a niece, who a fortnight later developed varicella. (2) Conversely varicella may be succeeded by zoster. (3) Zoster in one person may be followed after an interval of twelve to seventeen days, which corresponds to the incubation period of varicella, by an attack of the latter in children or others who have been in his company, or the converse may occur. (4) The identity of the two infections has been further established by Netter and Urbain, and more recently by Brain (4), employing the complement-fixation test. The serous contents or the crusts of the lesions of the two eruptions provide the antigen. Experiments with other vesicular eruptions, including herpes simplex, were negative. (5) The micropathology of the vesicles in herpes zoster and varicella is identical.

It is probable that in those cases of *H. zoster*, in which, apart from the main part of the eruption with radicular distribution, aberrant vesicular patches occur on various parts of the body, the cause is infection with the virus of varicella. As might be expected, in such cases the eruption appears to be part of a specific infective disease, there being prodromal fever, general malaise, and a leucocytosis with eosinophilia.

(b) Apart from the specific virus of varicella, it would seem certain that other infective organisms, reaching the ganglia by the blood-stream and causing inflammatory changes in them, may be causative. It is claimed that *H. zoster* has been produced in animals by injecting streptococci isolated from tonsils or infected teeth in persons suffering from the eruption. The writer has observed the case of a lady with supraorbital zoster, accompanied by rheumatoid arthritis, in whom injections of a vaccine prepared from streptococci isolated from her septic tonsils, provoked not only exacerbations of the arthritis, but also recurrent outbreaks of the herpes. Sande found gram-positive cocci in sections of the Gasserian ganglion taken from a case of herpes frontalis. No doubt the organisms of acute infections, such as pneumonia, may also invade and set up inflammation in the ganglia, thereby being the cause of zoster in some instances.

(c) Tuberculosis and syphilis of the spinal meninges may involve one or more posterior root ganglia. The writer has seen two cases of spinal caries, in which an attack of zoster occurred over an area corresponding to the nerve-roots of the affected part of the vertebral column. In syphilis it may be met with during the secondary period (sometimes, of course, being provoked by injections of salvarsan), there being signs of meningeal involvement; or it may accompany a syphilitic meningo-myelitis; and lastly, it is not uncommon in tabes and general paralysis. Cases of tabes have been observed in which *recurrent* attacks of zoster have taken place over a period of many months in an area affected by lightning pains.

(d) Certain toxic chemical substances may be responsible, *e.g.* arsenic, carbon monoxide, bismuth and mercury. Many cases were noted in the epidemic of arsenical poisoning among beer-drinkers that occurred in Manchester in 1900. It is sometimes met with in cases of psoriasis or other diseases, which are being treated by the oral administration of arsenic, but is more likely to be provoked by injections of the organic arsenical compounds.

(e) Traumatic zoster is sometimes seen, *e.g.* after injuries to the head or spinal column, lumbar puncture or spinal injections, and manipulation of the spine.

(f) New growths of the spinal column and meninges may invade the posterior root ganglia, as in the case recorded by Head and Campbell (5), in which an attack of zoster accompanied sarcoma of the vertebræ; post-mortem, invasion of the corresponding ganglia by the growth was revealed. In other cases it may occur in association with disease of the ribs; in one described by Dubler—tuberculous necrosis of the ribs—the ganglia were not involved, but an inflammatory neuritis of an intercostal nerve was found.

Morbid Anatomy. In the affected posterior root ganglia there is destruction of the ganglion cells, and degeneration in the posterior roots and columns and peripheral nerves. The vesicles of the eruption, which arise on an erythematous base, are structurally identical with those of varicella. They are formed in the rete Malpighii by intercellular œdema, and the epithelial cells undergo a peculiar "balloon" degeneration, whereby they become swollen and their nuclei multiply. In the corium there is vascular dilatation and œdema, with leucocytic infiltration, and some degree of necrosis, which may be intense enough to leave deep cicatrices. It has been suggested that these lesions in the skin, which clearly result from irritative changes in the sensory ganglia or the nerves distal to them, are due to the slow and continuous release of H-substance (probably histamine) in the area of skin affected (6).

Treatment. In mild cases all that is necessary is to keep the lesions dry and

clean by the application of a boro-talc dusting-powder, calamine lotion, or a simple zinc paste. Ointments, fomentations, and poultices should be avoided, since they favour secondary infection of the vesicles, and increase the liability to scarring. Intramuscular injections of a solution of pituitary extract, 0·5–1 c.c., have a remarkable effect not only in relieving pain, but also in shortening the duration of the attack. The injections may be repeated daily until pain has ceased. Pregnancy is the only contra-indication. Autohæmotherapy also appears to be of value. For the severe and intractable pain that may persist long after the attack, as a rule in old people, driving the patient even to suicide, deep radiotherapy of the corresponding roots is sometimes strikingly successful.

Bacterial Diseases. I. Micrococcal

In the great majority of diseases of the skin, in which the pathological changes are due to the active growth in it of micro-organisms, infection takes place from without ; it must be remembered, however, that even the healthiest and cleanest skin is never sterile, but harbours on its surface, and particularly at the mouths of the pilo-sebaceous follicles, at the muco-cutaneous junctions, and in its natural folds, a large number and variety of organisms. There are three organisms that are so constantly found in human skin, at any rate under civilised conditions, that they may, perhaps, be regarded as its normal inhabitants. They are the *Staphylococcus albus*, the *microbacillus* of *acne*, and the *pityrosporon* of *Malassez*, which is also wrongly termed the "bottle-bacillus" ; it is a yeast-like fungus, nearly related to *Monilia*. It cannot, however, be too strongly emphasised that the healthy skin must not be regarded as a hot-bed of microbial growth ; on the contrary it is remarkably amicrobial. Microscopical sections through absolutely normal skin show that organisms occur *as isolated units on the surface* of the horny layer, never penetrating even its superficial layers ; they are also seen lying at the mouths of the pilo-sebaceous follicles, but never in the sweat-ducts. However it is clear (7) that a distinction must be drawn between the mere presence of micro-organisms on the surface and their occurrence *in a state of active growth* ; except in certain moist folds, such as between the toes and in the axillæ, where organisms are normally in a state of vigorous multiplication (without, however, in health producing any effect beyond decomposing the secretions), there is no active microbial growth on healthy skin, whereas in the most minute pustule or other infective lesion organisms are present in enormous numbers. Moreover, in seborrhœa and comedo the sebaceous follicles contain myriads of *acne* bacilli, and in the scales of pityriasis simplex the *pityrosporon* can be seen in profusion.

The horny layer forms a natural protection against microbial invasion of the skin. When this is damaged, however slightly, an opportunity for such invasion occurs, and any micro-organisms present, either normally, *e.g.*, staphylococci, or accidentally, *e.g.*, streptococci, are liable to take on active growth and produce pathological effects. The pilo-sebaceous orifices may be looked on as weak points in the horny barrier, and the staphylococci that lurk there are likely to set up a folliculitis when the skin is damaged by an irritant.

It will thus be understood that diseases of the skin, caused by external infection, may arise from (1) active growth and invasion of organisms, already present in an inactive state, owing to damage to the skin or some other factor which lowers its resistance, *e.g.*, many forms of staphylococcal, and, to a less extent, streptococcal infections ; (2) direct or indirect contagion with virulent organisms from an infected person or animal, *e.g.*, impetigo contagiosa, ringworm, syphilis, warts and lupus verrucosus ; (3) invasion of the skin from infected mucous membranes, *e.g.*, impetigo from rhinitis or otorrhœa, sycosis of the upper lip from rhinitis or from spread, *via* the nasal duct, of a staphylococcal blepharitis. It is, moreover, obvious that once a focus of virulent bacterial growth has been established, the risk of invasion of other parts of the skin is greatly increased.

The skin may be invaded by organisms *viâ* the blood stream, *e.g.*, in pyæmia and septicæmia, in tuberculosis, syphilis, leprosy, suppurative ringworm, certain of the exanthemata, and probably, at least in some cases, in eruptions such as erythema multiforme, erythema nodosum, and purpura.

By far the commonest eruptions caused by external infection are those due to the pyogenic cocci, the acne bacillus, and the pityrosporon of Malassez, and the conditions caused by these organisms will be dealt with first. With regard to the pyogenic cocci certain differences between staphylococcal and streptococcal infections may be tabulated as follows :—

Staphylococci.

(1) Some strains may be considered as natural habitants of the skin.

(2) Tend to involve the pilo-sebaceous follicles, so that most staphylococcal eruptions are primarily follicular.

(3) Do not, as a rule, cause lymphangitis or adenitis.

(4) Are powerfully chemiotactic for polymorphonuclear leucocytes, thus producing "laudable pus."

(5) Staphylococcal lesions tend to remain *pure*, *i.e.*, do not usually become secondarily infected with other organisms.

Streptococci

(1) Are more likely to invade the skin either from some previous host, or from mucous membranes.

(2) Have no predilection for the follicles, but tend to involve the natural folds of the skin and to form fissures.

(3) Are prone to invade the lymphatics and cause adenitis.

(4) Are less pyogenic, and tend to provoke an exudation of serum containing only a few cells.

(5) Streptococcal lesions always become secondarily infected with staphylococci, which may then form primary follicular lesions—*e.g.*, a staphylococcal sycosis may follow a streptococcal impetigo.

STREPTOCOCCAL INFECTIONS

Impetigo is the term given to a superficial infection of the skin with pyogenic organisms, and is characterised by the formation of pustules or bullæ, appearing rapidly on healthy skin, the contents of which dry up to form crusts under which healing takes place. Instead of developing on healthy skin, infection with the same micro-organisms may complicate some pre-existing pathological lesions, particularly eczema, resulting in pus formation and subsequent crusting. Under these circumstances the lesions are said to have become secondarily *impetiginised*.

Of primary impetigo there are two distinct varieties : (1) *Impetigo contagiosa* (Tilbury Fox), due to infection with the streptococcus *pyogenes longus* ; (2) *impetigo of Bockhardt*, due to staphylococcal infection. It is preferable to reserve the term *impetigo* exclusively for the streptococcal variety ; the impetigo of Bockhardt may be conveniently named *porofolliculitis*.

IMPETIGO CONTAGIOSA (See Plate 58, A)

In this variety infection of the skin with the streptococcus takes place just beneath the horny layer. The primary lesion is a minute red spot, which very rapidly becomes a superficial vesicle or bulla, owing to the exudation of fluid, and the vesicles or bullæ may be considered as the characteristic lesions of the disease. Where the horny layer is thin, as on the face, they are flaccid, but in other parts, particularly on the palms and soles, they may be tense. In the early stage the contained fluid is clear serum, and from it the streptococcus may often be grown in pure culture, but secondary infection with staphylococci soon takes place, and the fluid then becomes cloudy from the presence of leucocytes ; in this stage the

vesicles are surrounded by a red halo of hyperæmia. The fluid may escape owing to rupture of the roof of the vesicle, or may dry up spontaneously ; in any case the dried serum forms characteristic crusts, which are yellow, or amber coloured, or sometimes brown from admixture with blood or dirt. After a few days the crusts fall, leaving a pink stain to mark the site of the original lesion. Should a crust be removed before healing has taken place beneath it, a raw, oozing, and sometimes bleeding surface is exposed, which soon becomes encrusted again. Healing takes place by complete regrowth of normal epithelium and no scar is left. The subjective symptoms are usually slight, but there may be some itching or burning, and in children fresh lesions are produced by scratching. Various types of impetigo contagiosa have been described.

In *impetigo circinata* there is comparatively little exudation, and the lesions tend to spread peripherally while healing in the centre, thus forming circinate patches with crusted margins ; the condition is often mistaken for circinate ringworm. By confluence of the patches extensive gyrate figures may result (*I. gyrata*).

Impetigo bullosa. In this variety the lesions form large bullæ, the roofs of which are flaccid, except where the horny layer is thick, as on the palms and soles.

Impetigo pityrodes. There is, as Sabouraud insisted in 1904, a dry, attenuated form of streptococcal impetigo, situated as a rule on the face, in which the lesions consist of dry, furfuraceous patches usually of irregular shape. They correspond probably to the majority of cases of the *dartre volante* or tetter of older authors. They are met with towards the end of an attack of ordinary impetigo, and one may see in the same patient all stages from the crusted, oozing lesions, to the dry, scaly patches referred to. They are, however, also very common in children suffering from chronic nasal catarrh, in whom there has been no definite attack of ordinary impetigo, and are then frequently associated with streptococcal fissures at the angles of the nostrils or mouth. Their occurrence is predisposed to by the use of strongly alkaline soaps, which damage the protective horny layer, but such soaps may of themselves give rise to dry, scaly patches apart from infection. Impetigo pityrodes is contagious, and many epidemics of it have been described. It has to be differentiated from the scaly patches caused by the pityrosporon of Malassez, which are usually seen in older children and adults, and from the eczematoid tuberculide.

Ætiology. The primary phlyctenule of streptococcal impetigo rapidly becomes secondarily invaded by the staphylococci always present in the mouths of the pilo-sebaceous follicles, and, as these organisms grow much more readily and abundantly than streptococci in ordinary media, cultures made even from early lesions of impetigo may give pure growths of staphylococci. In order to obtain the streptococcus, the serum from the early phlyctenule, or from the raw surface exposed after removal of a crust, is drawn up into a small glass pipette half-full of serum-broth, the ends are sealed, and the pipette incubated at 39° for about eight hours. If then the lower end of the pipette be broken, the first few drops of the medium will be found to contain the streptococcus in pure culture, whereas the fluid in the upper part in contact with air will contain staphylococci. The streptococcus, being a facultative anaerobe, will grow alone in the lowest portion of the pipette. When the phlyctenules or bullæ of impetigo occur on the palmar surface of the hand, where there are no pilo-sebaceous follicles and consequently staphylococci are less numerous, secondary staphylococcal invasion occurs relatively late, the serous contents of the phlyctenule tend to remain clear, and the streptococcus may be obtained in pure culture even on ordinary media. Culture media containing crystal-violet, which inhibit the growth of staphylococci, may also be used (8). By this means abundant growths of a streptococcus longus in ordinary impetigo and ecthyma are obtained, whereas in cultures from normal skin and from various other skin

eruptions, not of streptococcal origin, either no streptococci grow at all, or only a few isolated colonies. Sabouraud's contention as to the streptococcal causation of impetigo pityrodes is thus confirmed. The chief factors predisposing to impetigo are trauma of all kinds, whereby the horny layer of the skin is damaged, and exposure to infection with virulent streptococci. As its name implies, it is contagious, and is apt to be communicated from one member of a family to another by indirect and direct contact, and also occurs in epidemic form in schools and other communities. The so-called *scrum-pox* is impetigo contagiosa spread by contact on the football field. Apart from contagion, it may arise spontaneously, and is apt to complicate itching conditions, such as scabies, and particularly pediculosis capitis. Impetigo of the scalp is frequently due to the latter cause. It may begin around the nostrils, or on the upper lip, by infection of the skin with a streptococcus derived from an acute rhinitis or purulent nasal discharge, and around the ear from the discharge of a chronic otitis media. It frequently arises from fissures at the angle of the mouth (*la perlèche*).

Morbid Anatomy. Microscopical section through a vesicle shows that this is situated at the level of the stratum granulosum, so that the roof is formed by the stratum corneum and the base by the upper part of the prickle-cell layer. The fluid consists of serum containing leucocytes; chains of streptococci may be seen along the floor of the vesicle, and groups of staphylococci near the roof and sides. The epidermis beneath is œdematous, and leucocytes may be seen in the intra-epithelial lymph channels. The capillaries in the papillæ are dilated and there is slight inflammatory infiltration.

Prognosis. The prognosis varies according to the individual case. An acute attack of the disease occurring in a child or adult, otherwise in good health, tends to run a definite course of some three to six weeks' duration, recovery taking place spontaneously owing to the gradual development of immunity to the infecting streptococcus. On the other hand, in debilitated persons, particularly in those who suffer from a chronic streptococcal infection of their mucous membranes, so common among children of the poorer classes, or from otorrhœa, impetigo, usually associated with streptococcal fissures and intertrigo, may become a chronic disease. It is in these cases that, apart from chronic fissures at the muco-cutaneous junctions and in the natural folds of the skin, the dry scaly form of impetigo, already described, is likely to occur.

Treatment. Local. One of the best local applications for streptococcal impetigo is the eau d'Alibour of the French, of which various formulæ are employed. Sabouraud recommends:—

R	Zinci Sulphatis	1·0
	Cupri Sulphatis	4·0
	Aq. dest.	1000·0

This solution should be applied vigorously with swabs of cotton-wool, so as to remove the crusts and bring it in contact with the underlying infected surface. The applications should be repeated several times daily, until under their influence the thick yellow crusts are replaced by dry, superficial scales. The desiccating effect of this lotion may be mitigated by applying a weak ichthyol cream.

An alternative method is to swab the infected areas, after removal of crusts, with a solution of perchloride of mercury in 75 per cent. spirit (1 in 4,000). In either case, when desiccation of the lesions has occurred, a mercurial ointment or paste should be employed, *e.g.*,

	R	Hydrarg. Ammoniat.	gr. v.-x.
		Ung Paraffini	ad ̄i.
or	R	Hydrarg. Oxidi Flavi	gr. v.-x.
		Pasta Zinci Comp. B.P.	ad ̄i.

In extensive cases with much crusting preliminary applications of boric-starch poultices are of value, and, when the eruption is widespread, a tablespoonful of

zinc sulphate should be added to the daily bath. It is of great importance to treat infection of the adjacent mucous membranes and any fissures that may be present.

As has been said, recovery from an attack of impetigo probably depends more on the development of immunity than on the efficacy of local treatment. In early cases it is worth while trying to abort the attack by the judicious employment of a mixed streptococcal and staphylococcal vaccine, prepared from strains of organisms obtained from impetigo lesions. A vaccine is also of value in cases in which fresh lesions continue to appear despite adequate local measures, and in those of long-standing. A completely out-of-door life by the sea or in a bracing climate should be enjoined when possible, and is almost imperative in chronic cases, in which the most careful local treatment usually fails to prevent recurrence.

As has been said, impetigo contagiosa is often spread by indirect contact through the medium of towels, shaving brushes, etc.

ECTHYMA

This condition may be regarded as a deep form of streptococcal impetigo, in which destruction of the epidermis occurs, and an ulcer results. The lesions begin as pustules or bullæ containing serum, which, as in ordinary impetigo, is either cloudy or, more rarely, frankly purulent according to the degree of secondary staphylococcal infection; the serum dries to form a thick, adherent crust of a dirty yellow colour, or reddish-brown from admixture with blood, and sometimes almost rupial in character. Around the crust may be seen in comparatively early lesions the shrivelled roof of the original bulla, and beyond this a red area of inflammation, with sometimes considerable œdema. On removal of the crust the underlying ulcer is exposed. It is not, as a rule, very deep, its borders are sharply defined, and its base is red; from it exudes a purulent or sero-sanguinous fluid, containing tissue-débris, elastic fibres, altered red blood corpuscles, leucocytes, and cocci. Under suitable conditions and treatment the lesions dry up, the crusts are shed, and the ulcers heal, leaving scars, usually surrounded by a pigmented border. Ecthyma is most frequently seen on the legs, the buttocks, particularly in infants, and the back; circulatory stasis is an important contributory factor, so that it is apt to occur on varicose legs, and may be the starting point of a varicose ulcer. General debility, acroasphyxia, alcoholism, and diabetes are predisposing causes, and the condition may complicate a pruritus, scabies, and pediculosis. During the war it was a cause of much disability among our louse-ridden soldiers, and the streptococcus *fæcalis* appeared often to be the infecting organism (MacCormac).

Morbid Anatomy. The ulcerated lesion shows necrosis, leucocytic infiltration and intense congestion of the dermis, with dilatation of the vessels, which are surrounded by sheaths of cells.

Treatment. The local treatment should be carried out along the lines already suggested for impetigo. In obstinate cases exposure of the lesions to sunlight or the ultra-violet rays will usually hasten healing. In debilitated persons prolonged rest out of doors, and the administration of tonics, particularly the *Syr. ferri iodidi* B.P. and the *Syr. calcii lactophosphatis* B.P., are indicated.

DERMATITIS GANGRENOSA INFANTUM

This very rare condition has already been referred to under the name of *varicella gangrenosa* (see p. 35), but, although it is usually a sequel of chicken-pox, it may follow other eruptions, such as vaccinia and the infective dermatitis known as "napkin-rash." It occurs usually in marasmic infants, enfeebled by previous acute disease, improper feeding and neglect, rickets or tuberculosis, but

it has been seen in well-cared-for children. The lesions consist of sharply punched-out ulcers often covered by a black slough; they may heal, but in severe cases extend peripherally, producing vast areas of gangrenous ulceration. The children as a rule are acutely ill, with high fever; death results from pyæmia and septic bronchopneumonia. In cases that recover permanent widespread scarring is, of course, present throughout life.

Ætiology. Probably the original infecting organism is, as in ordinary ecthyma, a streptococcus pyogenes longus, but secondary invaders, such as staphylococci, doubtless play an important and sometimes predominant part. There is considerable evidence that infection with the *Bacillus pyocyaneus* may in some cases, at any rate, be responsible for the development of the condition.

Treatment. The same principles should be followed as indicated under pemphigus neonatorum.

INTERTRIGO

The eruption known as intertrigo (*erythema intertrigo*, *eczema intertrigo*) is the inflammatory redness which occurs in the natural folds of the skin, for example in the groins, between the buttocks, in the axillæ, under the mammæ, behind the ears, and in fat people in the hypogastric fold and around the neck. In its simplest form the eruption corresponds closely to the parts of the skin that are in contact; the surface is raw, denuded of the upper layers of the epidermis, and it secretes a whitish, turbid fluid, different from the yellow serum or sero-pus of eczema, and not drying into crusts, unless mixed with the medicinal substances applied to it. At the bottom of the fold is often a fissure, which is easily seen when the opposing surfaces are separated. Intertrigo may give rise to no subjective symptoms, but sometimes itching is complained of, and secondary eczematization, with lichenification, may result from constant scratching.

Ætiology. The mechanical friction of two opposed surfaces of skin, the accumulation and decomposition of secretions, and the moisture of the parts are predisposing factors; it is obvious, therefore, that lack of personal cleanliness and obesity favour the development of intertrigo. Apart from these predisposing factors, however, the essential cause of intertrigo is infection of the surface of the skin in the fold or folds involved, and this may be due to different kinds of organisms. Thus we recognise varieties due to infection with (1) a streptococcus, (2) certain species of ringworm fungus, *e.g.*, the epidermophyton inguinale (*eczema marginatum*, *tinea cruris*) and the microsporon minutissimum (*erythrasma*), (3) yeast-like organisms of the genera monilia (or oïdium), cryptococcus, saccharomyces or endomyces—the oïdiomycoses—including the pityrosporon of Malassez. The diagnosis of erythrasma and of epidermophytosis is not, as a rule, difficult; they will be dealt with in a later section. On the other hand, the differentiation between a streptococcal intertrigo and that due to the oïdiomycoses may be impossible without careful microscopical examination of scrapings and cultural investigation.

Probably, as Sabouraud maintains, the majority of cases of simple intertrigo are of streptococcal origin. Certainly is this so in retroauricular intertrigo. In the axis of the fold is found a fissure, on either side of which the appearances are those of a streptococcal impetigo, or of a simple intertrigo as seen in other folds; that is to say, there may be impetiginous crusts, removal of which exposes a moist, pink surface, as in ordinary impetigo, with extension of the infected area beyond the actual fold, or the infection may be strictly limited to the fold, with no crust-formation. Such a streptococcal intertrigo may also be seen in the groins, the hypogastric fold, the internatal cleft, where it may be the cause of pruritus ani, the axillæ, and submammary fold in women. In intertrigo due to the yeast-like group of organisms, there is a greater tendency to extension of the infection, and a widespread dermatitis far beyond the limits of the folds may

result. This variety will be described later. It must be remembered that *psoriasis* may involve the flexures, and in some cases closely imitate an intertrigo of infective origin

Treatment. In streptococcal intertrigo it is essential that the central fissure be completely healed, as otherwise relapse is certain to occur. One of the simplest and most effective methods is to apply a 1 per cent. solution of iodine in spirit vigorously on a cotton-wool swab once or twice daily to the infected area, and after each application a simple zinc cream may be smeared in the fold. The treatment must be continued until the new horny layer is completely restored. In some cases, particularly if the central fissure is deep and resistant, a 2 per cent. solution of silver nitrate in spt. ætheris nitrosi is to be preferred to the iodine. In mycotic intertrigo the iodine solution is also very effective.

Needless to say, scrupulous cleanliness, the separation of the opposing surfaces of the fold, and the use of a mild antiseptic dusting powder are indicated as prophylactic measures. There is no doubt that a sedentary life, an excessive dietary, particularly of carbohydrates and fats, and overclothing are often predisposing factors in the intertrigo so common in the folds of obese persons, and, apart from dietetic restrictions and regular exercise, the internal administration of alkalies often seems to be of value.

Chronic retroauricular intertrigo is common in children, and is usually seen in those suffering from chronic nasopharyngeal catarrh, impetiginous anterior rhinitis, and the dry, scaly form of impetigo of the face. An open-air life by the sea, a generous dietary of vitamin-rich foods, and a course of real or artificial heliotherapy should be prescribed for these cases.

STREPTOCOCCAL FISSURE

As has already been stated, streptococci are prone to infect the folds of the skin, and to produce fissures therein and at the mucocutaneous junctions; in the latter situations the mucous membrane is often the primary source of infection. Thus fissures in the naso-labial folds are usually secondary to an acute or chronic rhinitis, and those at the labial commissures—which form the starting point of *la perlèche*—may result either from a streptococcal stomatitis, gingivitis, or pyorrhœa, or from maceration with infected saliva in children who dribble. Fissures are also common in the retroauricular region (retroauricular intertrigo) and beneath the lobes of the ears.

Retroauricular intertrigo is often wrongly diagnosed as eczema, or seborrhœic dermatitis; it provides a very good example of chronic streptococcal infection of a natural fold. Behind one or both ears is seen a moist, crusted area, and beneath the crusts the surface is bluish-red; at the angle of the fold is the fissure, which divides the infected area into two halves, and is exposed on drawing the ear forward. Sometimes at the margin may be seen remains of the original streptococcal vesicle in the form of a shrivelled fragment of the raised horny layer.

La perlèche, or intertrigo of the labial commissures, may be confused with the mucous patches of syphilis and with labial herpes. It consists of a fissure at one or both angles of the mouth with a V-shaped inflammatory area spreading outwards, and covered with macerated greyish-white epidermis. It often co-exists with impetigo contagiosa, and may, like other streptococcal fissures, be a source of reinfection. It is contagious, being spread by kissing or by the exchange of pens and pencils, which have been held in the mouth of an infected person. It is often associated with dyspepsia of the fermentative type, due to an excessive carbohydrate dietary.

Treatment. A streptococcal fissure should be painted with a 2 per cent. solution of silver nitrate in spirit, ætheris nitrosi, and then smeared with a mercurial paste. In resistant cases fractional doses of X-rays are of value.

RELAPSING STREPTOCOCCAL LYMPHANGITIS

This condition occurs most commonly on the face or around the ears. The malar regions and upper lip are common sites. Clinically it resembles ordinary erysipelas, the affected area being swollen, reddened, and somewhat shiny. There is usually little or no constitutional disturbance, owing to the slight virulence of the infecting streptococcus. Exposure to cold wind may provoke an attack. From repeated attacks permanent blocking of the lymphatics may result, with the production of one form of elephantiasis nostras. Persistent swelling of the upper lip and malar regions is not uncommon from this cause. Recurring attacks of lymphangitis involving the feet, ankles and legs, are also met with in association with streptococcal fissures between the toes. These fissures are almost always secondary to epidermophytosis of the feet (*q.v.*). Unless permanent blockage of the lymphatics has already occurred, efficient treatment of the epidermophytosis will be curative.

Ætiology. The condition is due to streptococcal infection of the lymphatics of the part. In most cases there is present a streptococcal fissure from which reinfection periodically takes place. In some cases there is no external fissure, but, as a rule, some chronic focus of streptococcal infection in the mucous membranes of the mouth or nasopharynx, or in the nasal sinuses, is present.

Treatment. If a streptococcal fissure is responsible, its cure will lead to a cessation of the attacks. In other cases any source of streptococcal infection in the mouth, nose, or nasopharynx should be sought for and treated. When persistent elephantiasis has supervened, removal of the original source of infection may be followed by a gradual disappearance of the swelling, but not always. Repeated small doses of X-rays to the area affected are sometimes of benefit. Intradermal injections of a streptococcal vaccine, either autogenous or prepared from various stock strains, are of undoubted value, even when persistent blockage of the lymphatics is present. The initial dose should be small— one to two million organisms—and the subsequent dosage depends on the degree of local reaction at the site of injection, which is usually severe, often leading to abscess-formation and necrosis. So long as this is marked, the dose should not be increased.

ECZEMATOID STREPTOCOCCAL ERUPTION OF THE SCALP

(*Fausse teigne amiantacée d'Alibert*)

This condition is frequently seen on the scalp in association with streptococcal retro-auricular intertrigo, but may occur without any infective lesion of the skin. It may be widespread over the surface of the scalp, or localised, often to the vertex. It is characterised by a whitish lamellar crust, composed of silvery scales, which mat the hairs together, and, when the entangled hairs are lifted up, the scales become dissociated and cling to the hair-shafts. The under surface of the crust is yellowish, in contrast with the silvery whiteness of the upper portion, owing to admixture with serum. After removal of the crust, the underlying epidermis appears smooth and slightly pink, and droplets of serum exude when this is gently scraped.

The eruption is therefore eczematoid in nature, but the serous exudation is minimal, whereas the formation of parakeratotic scales is the striking feature.

Ætiology. Its frequent association with retro-auricular intertrigo, particularly when the infection tends to spread upwards to the lateral surfaces of the scalp, indicates its streptococcal origin, and Sabouraud states that streptococci appear in cultures from the deeper layers of the squames. When this is so the condition may be regarded as an eczematoid reaction to the local growth of streptococci. In some cases, however, cultures have yielded only a *Staphylococcus albus* even when special media have been utilised and when streptococci

have been grown in abundance from the neighbouring intertrigo. Moreover, similar cases have been observed in which the latter was absent, but a chronic focus or foci of streptococcal infection were present elsewhere, *e.g.*, in a nasal sinus, successful treatment of which appeared to benefit the eruption. It is therefore likely that it may be sometimes a true eczematoid streptococcide, *i.e.*, an epidermal reaction to streptococcal toxin absorbed from a distant focus of infection either in the skin or elsewhere.

Treatment. The scales should be removed and to the affected area should be applied an ointment containing oil of cade, or ammoniated mercury and liq. picis carbonic B.P. If retro-auricular intertrigo be present, this should be treated along the lines already suggested. In every case other possible foci of streptococcal infection should be sought for.

INFANTILE ERYTHEMA OF JACQUET

(*Napkin Rash*)

Under this title is known a form of dermatitis, which is common in the napkin area of infants, and which may be considered as a variety of intertrigo. The eruption occurs on the buttocks, lower abdomen, genitals, and inner sides of the thighs, *i.e.*, on the areas in which there is friction from the napkin. It may also be seen on the calves and on the parts of the thighs opposed to them when the child lies with its legs drawn up, and also on the heels. In the early or erythematous stage the appearance is that of ordinary intertrigo, but the colour may be of a curious reddish-coppery hue; vesicles may then appear, leading to the formation of erosions, which, in turn, may be transformed into flat red papules, resembling somewhat those of congenital syphilis; lastly, the erosions may terminate in punched-out ulcers, which often coalesce.

Ætiology. In the majority of cases the condition is associated with "the ammoniacal diaper." It has been shown (9) that the ammonia is produced by a saprophytic organism present in the fæces of many infants as well as of older children and adults, the *Bacillus ammoniagenes*, which possesses the power of forming free ammonia from urea [$\text{CO}(\text{NH}_2)_2 + 2\text{H}_2\text{O} = (\text{NH}_4)_2\text{CO}_3 = 2\text{NH}_3 + \text{H}_2\text{O} + \text{CO}_2$]. The primary causal factor is the irritation of the skin by the ammonia thus produced in napkins soiled with urine and fæces, and consequently the dermatitis is limited to those areas of skin that come in contact with the wet napkin.

The eruption is relatively rare in breast-fed infants, as in them the normal acid stools are less favourable for the growth of the *B. ammoniagenes*. On the other hand, in infants fed on a rich protein diet, and with alkaline stools, this organism thrives, and it is in them that the condition is most commonly met with. Infrequent changing of the napkins and carelessness in keeping the buttocks clean are naturally predisposing factors. The irritation by the ammoniacal diaper at first causes an erythema, which may be followed by desquamation; in long-standing cases the action of the alkali renders the skin harsh, dry and thickened, the appearances resembling those of "washerwoman's dermatitis." The damage sustained by the horny layer naturally favours invasion by pyogenic organisms, particularly streptococci, which are probably responsible for the secondary lesions—vesico-papules and pustules, and ecthymatous ulcers. Sabouraud, in fact, regards Jacquet's dermatitis as a streptococcal impetigo and ecthyma, but the primary damage to the skin by ammoniacal diapers is the essential cause. It should be remarked that an identical condition may arise in older children with nocturnal enuresis, and in adults with urinary incontinence; the ulceration that may occur around the meatus of circumcised male infants is also due to irritation of the exposed glans by the ammoniacal diaper.

Diagnosis. The importance of the eruption lies in the fact that in its severer forms it may easily be confused with a congenital syphilitic eruption,

and Parrot, who first described it, wrongly attributed it to syphilis. The main points in the differential diagnosis are that a napkin rash occurs on parts exposed to pressure and friction, and not on the flexures, which are protected from contact with the napkin; there are no lesions on the palms and soles, the colour of the eruption is less coppery, and mucous patches on the anus and at the angles of the mouth are absent. Nevertheless, doubtful cases are met with, and careful investigation for syphilis should then be made both in the parents and child.

Treatment. Cooke has shown that the impregnation of the diapers with an antiseptic, thus inhibiting the growth of the *B. ammoniagenes*, is rapidly effectual. He recommends that, after washing, the diapers should be rinsed in a 1 : 4,000 solution of mercuric chloride, prepared by dissolving one 7½ grain tablet in two quarts of water. They are then wrung thoroughly, and allowed to dry. As an alternative a saturated solution of boric acid may be used in the same way, which, though less efficacious, obviates the risk of careless handling of so harmful a poison as mercuric chloride. Mild cases respond to this preventive treatment alone, but when erosions and ulceration are present, Lassar's paste, to which ammoniated mercury (5 grains to the ounce) may be added, should be freely applied. The diet should be modified with a view to restoring the normal acid reaction of the stools.

STAPHYLOCOCCAL INFECTIONS

The great majority of staphylococcal lesions of the skin are primarily follicular, and, in order clearly to understand their morbid histology, the general structure of the pilo-sebaceous follicle must be considered. It is formed by an invagination of the epidermis, like the finger of a glove, extending obliquely from the surface through the dermis, in which it is embedded. The depth of the follicle is proportional to the size of the hair that it contains, the larger the hair the deeper the follicle. Many of the deepest follicles extend to the subcutaneous fatty layer. The sebaceous gland arises obliquely from the follicle at a point situated one-third of its depth from the surface. At the bottom is the dermic papilla, from the epithelial covering of which the hair is formed. A pilo-sebaceous follicle may conveniently be divided into three portions: (a) The mouth or *ostium*, at the point of emergence of the hair; (b) the *infundibulum*, lying between the ostium and the opening of the sebaceous gland—this constitutes the upper third; (c) the portion between the infundibulum and the papilla. In this, the lowest two-thirds, the hair is closely in contact with the epithelial lining, but in the infundibulum there is a virtual space between the two, and it is here that the acne bacillus grows in seborrhœic persons. The ostium is the widest part of the follicle, forming a cup-like depression on the surface of the skin, and often separated from the infundibulum by a slight constriction. In the ostium are found, lying amidst the epithelial *débris*, a few staphylococci, which under favourable conditions multiply and produce inflammatory lesions. Moisture and heat are particularly likely to excite active germination of these staphylococci; hence the frequency of pustulation in regions such as the groins and armpits, and the noxious influence of poultices and fomentations.

Staphylococci are divided into three main groups, according to the colour of their growth on artificial media, viz., *S. albus*, *S. aureus*, and *S. citreus*. The depth of colour is to some extent an index of their virulence, as is their hæmolytic power. The *S. albus*, the least virulent, is a normal habitant of the human skin. Different strains or modifications of this organism have been described and it varies in virulence from a harmless saprophyte to a definitely pyogenic organism (10). It is found in a state of active growth, in association with the pityrosporon of Malassez, in the so-called *Pityriasis steatoides* and in *Seborrhœic dermatitis* (q.v.); it is the cause of the common and mild follicular pustule, of the

pustules that often arise after epilation for hypertrichosis, of some cases of porofolliculitis, and of some stitch-abscesses. Very rarely it may be the causal organism in sycosis. The *S. aureus* is almost constantly responsible for the more serious and chronic staphylococcal lesions of the skin, and, of course, for osteomyelitis and staphylococcal septicæmia. It is the cause of the more severe form of porofolliculitis (impetigo of Bockhardt), of boils and carbuncles, sycosis, the majority of cases of infective eczematoid dermatitis, hydradenitis, the multiple abscesses of infants, many cases of perionychia, granuloma pyogenicum, pemphigus neonatorum, and, in association with the microbacillus of acne, of acne necrotica. The *S. citreus*, intermediate between the other two species as regards virulence, is occasionally found in place of *S. aureus*. A characteristic of the more virulent staphylococci is their tendency to produce *necrosis*, such as occurs in boils, carbuncles and, more superficially, in some cases of porofolliculitis, and in acne necrotica.

Although the *S. albus* is constantly present in the skin, this is not true of the other two varieties. The *S. aureus* may sometimes be cultivated from the clean skin of normal persons, but its presence usually indicates either that the subject is suffering from some active pyogenic lesion, or that he has been in contact with some one thus infected. In either case he has become a "pyococcus-carrier." Once an active infection with a pyogenic staphylococcus has occurred, the organism becomes, so to speak, sown in the mouths of the pilosebaceous follicles, not only in the neighbourhood of the actual lesions, but also in parts widely distant from them. This fact is of the highest importance, both because fresh lesions, *e.g.*, boils, are likely to arise in different parts of the body so long as the pyococcus is present in the skin, and because the subject is a potent source of infection to others. As will be seen later, the pyococcus-carrier is the cause of most if not all the epidemics of pemphigus neonatorum. It follows from this that in cases of recurrent pyogenic infection of the skin, such as furunculosis, surface antisepsis is the first essential of rational treatment.

STAPHYLOCOCCAL PUSTULE

(*Porofolliculiticus*)

The simplest and commonest staphylococcal lesion of the skin is the small, superficial pustule, formed at the ostium of a pilosebaceous follicle, and caused by a *S. albus*. The organisms, lying latent in the ostium, under the influence of some trauma, *e.g.*, the application of an irritant, friction, shaving, etc., begin to grow actively, and form a mulberry-like mass. With their multiplication their toxins are presumably liberated, and cause a migration of polymorphonuclear leucocytes from the vessels in the dermis, which pass through the deeper layers of the epidermis, squeezing themselves between the Malpighian cells, towards the site of infection, and forming an *intra-epidermic* cavity—the *pustule*—having for its roof the horny layer and for its base the underlying rete Malpighii. This pustule usually arises at the side of the ostium, but quickly surrounds it, thus forming a ring around the hair, which pierces its horny roof. At the point of emergence of the hair the dome-like roof is umbilicated. Healing takes place by the desiccation of the pustule with the formation of a crust, which is exfoliated as a new horny layer is formed beneath it.

The simplest and most benign pustules of this type arise owing to the awakening into activity of the *S. albus*, already present at the mouths of the pilosebaceous follicles. The so-called *impetigo of Bockhardt*, better termed *acute porofolliculitis*, is merely an eruption of numerous follicular pustules due in mild cases to the *S. albus*, in the more severe to the *S. aureus*. The eruption usually follows the application of some irritant, such as liniments, plasters and blue ointment, particularly to hairy parts. An acute outbreak is often provoked around a discharging boil or septic ulcer as a result of fomenting or poulticing, the moisture,

heat, and maceration of the skin providing the staphylococci with conditions ideal for their active growth. In children, recurrent acute attacks on the scalp are not infrequent, and due, as a rule, to *S. aureus*. Each fresh attack is heralded by enlargement and tenderness of the occipital glands, and this is followed by the appearance of numerous pustules of varying size, yellowish or greenish-yellow, and each pierced by a hair. With their development the glandular enlargement subsides. In some of the pustules the infection spreads deeply and produces an area of *necrosis* in the dermis. This is revealed clinically by the presence of a greenish plug, embedded in the follicle, which cannot, unlike the overlying pustule, be wiped away after incising the horny layer. This plug or sphacelus is comparable to the core of a boil, and like it is the result of necrosis—consequently when the lesions heal there are left small circular pitted scars similar to those of acne necrotica. Another complication that may result from the simple, superficial follicular pustule is the development of an abscess, which is formed in the dermis around the follicle at a point about midway between the ostium and the bulb—the so-called hour-glass abscess. From this point the infection may spread laterally and produce an abscess of considerable size.

Treatment. In the treatment of superficial staphylococcal pustulation it must be emphasised that one's object is, first, to aid the desiccation of the lesions and, secondly, to disinfect both the area involved and the surrounding skin. For this purpose, as a rule, all that is necessary is to paint on once or twice daily a dilute solution of iodine in spirit, *e.g.* R. Tinct. iodi mitis, 1·0 ; Spt. vini meth. indust., ad 5·0 ; and to keep the infected area powdered with the pulv. acidi salicylici comp., B.P.C. If there is much pain or discomfort, calamine lotion, should be substituted for the powder. In the more severe or recurrent form of porofolliculitis, which is often accompanied by boils or abscesses, everything possible should be done to raise the patient's resistance to infection. An out-of-door holiday with judicious sun-bathing is the best treatment ; failing this, total ultra-violet light baths should be ordered. It is important to attempt to disinfect the whole skin by antiseptic baths as in furunculosis.

MILIARIA RUBRA

(*Prickly heat : Lichen tropicus*)

This eruption is most commonly seen in Europeans who inhabit tropical countries, but negroes are never affected. It occurs in temperate climates in those who perspire freely and who are seborrhœic. It consists of innumerable minute red spots, with tiny central vesicles containing a turbid fluid. These spots are hardly elevated, and they are not as a rule follicular. The trunk and the proximal segments of the limbs are the sites of predilection. Histologically there is seen to be congestion, with the presence in the rete of minute vesicles, formed either, as in impetigo, by cleavage or, as in eczema, by spongiosis ; these vesicles contain numerous polymorphonuclear leucocytes, and arise frequently, though not invariably, around a sweat-duct ; they are not, as Pollitzer stated, due to dilatation of the ducts.

Ætiology. The eruption is commoner in males than females, and appears suddenly after profuse sweating, provoked by a rise of temperature, the taking of hot alcoholic drinks, a hot bath, or violent exercise. The vesicles contain staphylococci in a state of active growth, and Darier's view that the eruption is due to an auto-inoculation of the skin with these organisms, caused by maceration of the epidermis with sweat, is probably correct. As he points out, there is frequently present some active infective focus, such as a boil, impetigo, seborrhœic dermatitis, acne pustules, etc. As predisposing factors may be mentioned the seborrhœic state, the wearing of excessive clothing (and particularly of flannel next the skin), overeating and dyspepsia, and the abuse of alcoholic

drinks. The fat, plethoric, cocktail-drinking European in the tropics is the commonest victim.

Treatment. A brisk purge, twenty-four hours' starvation, copious drinks of barley water and fresh lemon juice, and the administration of alkalies in large doses will rapidly cut short an attack. Locally, tepid baths containing zinc sulphate ($\frac{1}{4}$ lb.), followed by the application of a boro-talc powder, will suffice. Recurrence can be prevented by instituting a rational dietary, the avoidance of alcohol, the wearing of light, porous clothing, the taking of alkaline drinks, regular bathing, and the habitual use of a boric dusting powder.

BOILS

(*Furuncles. Furunculosis.*)

A boil is a massive folliculitis, due almost invariably to the *Staphylococcus aureus* (rarely *S. citreus*), and characterised by the intensity of the inflammatory reaction and by necrosis. It commences with a painful, red, and slightly raised spot, which gradually enlarges, becomes hard and tender to the touch, and is accompanied by induration and sometimes by a considerable œdema of the surrounding skin. The colour becomes dusky red, and after a few days the apex softens, a little pus being extruded and later a greenish-yellow slough of necrosed tissue--the *core*. When this has separated the inflammation subsides, and the sore gradually heals by granulation, leaving a small scar.

Boils may be situated on any portion of the skin where hair-follicles are present, but their sites of election are the back of the neck, the buttocks, the back, the thighs and forearms. Of particular importance are those occurring on or near the upper lip, owing to the fact that infection may spread to the cavernous sinus, and result in septic thrombosis, with ultimate pyæmia and death. In the external auditory meatus they give rise to intense and radiating pain; in this situation they often complicate a chronic seborrhœic dermatitis of the meatus.

Morbid Anatomy. A boil arises in a manner comparable to the more severe necrotic form of porofolliculitis. The staphylococci, growing first at the mouth of the follicle and producing a superficial and transitory pustule, spread downwards along the hair in long chains to form another centre of activity in the deeper part. Here they give rise to an enormous colony, around which necrosis of the follicular tissue and surrounding part of the dermis occurs. This necrotic mass, which is the *core*, has for its centre the colony of staphylococci, included in the remains of the follicle, and around this is a mass of fibrin, enmeshing masses of polymorphonuclear leucocytes, together with the disintegrated connective and elastic tissue of the dermis. The leucocytes nearest to the microbial colony are broken up, while in those further away the contours and nuclei are still intact. The mode of formation of a boil shows that it always results from an *external* infection of a follicle, and that the infection remains intrafollicular, but produces necrosis of tissue at a distance.

Ætiology. The *S. aureus* cannot be regarded as a normal habitant of clean healthy skin, but exposure to contamination with it must be very frequent. Although not so contagious as streptococcal impetigo, active lesions due to this organism are certainly a potent source of infection to others either by direct or indirect contact. Nurses and doctors not infrequently develop furunculosis from attending patients with this disease. Boils, porofolliculitis, and sycosis are also often contracted in the barber's shop. Once the skin is contaminated, irritation of the follicles, in which the staphylococci lurk, predisposes to their active growth; boils are therefore common at sites of friction, such as the back of the neck and the buttocks, and hence their frequency in the latter situation in horsemen and oarsmen, and on the forearms and backs of the hands in those who follow certain trades. The seborrhœic skin undoubtedly favours the growth of

the *S. aureus*, as well as of the *S. albus*, pityrosporon, and acne bacillus. Hyperglycæmia, too, is a notorious predisposing factor, but it must be remembered that boils and carbuncles, like other infections, may themselves cause a rise in blood-sugar, which falls to normal when the active infection subsides. An unhygienic indoor life, overwork, anæmia, an excessive or inadequate dietary, and chronic infections elsewhere are also factors operative in certain cases. A localised pruritus, *e.g.*, pruritus ani, is sometimes a predisposing cause, for which inquiry should always be made. In such cases the boils occur chiefly in the neighbourhood of the irritable area—on the buttocks and in the perinæum with pruritus ani—the constant or repeated scratching of the parts causing abrasions of the skin and disseminating the staphylococcus.

Treatment. The presence of a boil implies the probability of a widespread dissemination of the *S. aureus* in the ostia of the pilosebaceous follicles, and the first essential of treatment is to disinfect the skin over a considerable area around the boil by painting daily with diluted tincture of iodine, as recommended for porofolliculitis, and to attempt a more general disinfection of the whole skin by the addition of an antiseptic to the daily bath, *e.g.*, 4 oz. of zinc sulphate, or of such preparations as lysol, cyllin, monsol, etc. Many chronic cases of furunculosis respond to this simple method of surface antisepsis, when more elaborate treatment by means of vaccines, collosol manganese, etc., have failed. An incipient boil may sometimes be aborted by making a small incision with a fine von Graefe knife, and plunging through this into the centre a sharpened match-stick dipped in pure carbolic acid, monsol, or lysol. When the active stage of inflammation has subsided, the greatest care must be taken to remove the core entire—to break it up on the surface of the surrounding skin is to risk disseminating living staphylococci contained in its centre. *In no circumstances should a boil be treated by poultices or boric fomentations*, for reasons already stated; if pain is very intense in the early stages, hot fomentations with a 1/4,000 solution of perchloride of mercury for a short period are admissible, but they should not be employed if the skin has already been painted with iodine. It is preferable to apply a layer of pure ichthyol to a developing boil and cover with cotton wool, or it may be dressed with magnesium paste (magn. sulph. exsicc. 2·0, glycerine 1·0). In addition to the local application of dilute iodine and ichthyol, and a daily antiseptic bath, the pulv. acidi salicylici comp., B.P.C., should be dusted on the skin surrounding the boil and in the joint flexures.

General Treatment. Although local and general disinfection of the skin is of primary importance, and often alone suffices, there may in many cases be indications for internal treatment. It is important to examine carefully for focal infection in the teeth, tonsils, nasal sinuses, or elsewhere, for this is sometimes responsible for lowering the resistance to the staphylococcus. Hyperglycæmia must, of course, be dealt with by suitable dietary and, if necessary, injections of insulin. In plethoric seborrhœic persons a restricted carbohydrate dietary and full doses of alkali are indicated; on the other hand, in debilitated, anæmic persons, in whom phosphaturia is common, iron should be given and acidosis produced by acid sod. phosph. (see p. 538). In obstinate cases a complete holiday in the open air must be insisted upon, and this should be combined with real or artificial sun-baths. Given in suitable and increasing doses, heliotherapy provides one of the best methods of raising the resistance to staphylococcal infection. Injections of a stock or autogenous staphylococcal vaccine, provided the dosage be carefully controlled, are of undoubted value in furunculosis, but cases are met with in which they fail or actually do harm. Less certain in their effect are injections of collosol manganese or manganese butyrate, and the oral administration of tin (stannoxy). Fresh brewers' yeast, 1 to 2 oz. per diem, may be tried with advantage. Lastly, autogenous whole-blood injections have been claimed as almost a specific in resistant cases. To sum up, the successful treatment of furunculosis depends first on local and general disinfection of the

skin, and secondly on the correction of any factors that are lowering the patient's general health, combined, if necessary, with specific vaccination and heliotherapy.

CARBUNCLE

This is a similar infection by staphylococci, leading to extensive inflammation, induration, and necrosis of the skin and subcutaneous tissue. It differs from a boil in its extent, and in the fact that there are numerous foci of suppuration, leading to discharge through several openings instead of one. The patients are generally of middle age or older, and diabetes mellitus is a very common antecedent. The common seat of the lesion is the back of the neck, but it also occurs often on the back. It begins as a flat, indurated area of red or purplish-red colour; this extends and becomes more elevated above the level of the skin, spots of softening occur, and discharge of pus takes place. The hard mass forms a slough, which comes away, leaving a deep ulcer; and this ultimately heals by granulation, producing a scar. A carbuncle may be from 1 to 3 inches in diameter, and occasionally very much more. There is much constitutional disturbance, with pyrexia; septic infection is likely to occur, or death may take place from exhaustion.

Treatment. In the early stages, both of furunculosis and carbuncle, intramuscular injections of *aolan*—a proprietary preparation of lactalbumin—which produces a leucocytosis, will as a rule mitigate the severity and hasten the evolution of the lesions. From 5 to 10 c.c., or more in threatening carbuncle, should be injected into the muscles of the upper and outer quadrant of the buttock daily or every other day, three to five injections being given. In severe cases of carbuncle, particularly in debilitated persons, complete excision may be advisable; otherwise the measures advised for boils should be employed.

PEMPHIGUS NEONATORUM (*See Plate 58, C, p. 833*).

This disease, first described in France by Ochène, is a comparatively rare contagious affection of the newly-born, and has by many been regarded merely as a variety of bullous impetigo occurring in infants. Sabouraud still inclines to this view, and considers that, like ordinary impetigo, it is primarily of streptococcal origin. That a bullous *streptococcal* impetigo may occur in infants, as well as in older children and adults, is certain, but the independent observations of several workers indicate that the true pemphigus neonatorum, like the rare form of bullous impetigo described by Jadassohn, is usually, at any rate, due to infection with *Staphylococcus aureus*.

The eruption, which appears, as a rule, from the fourth to the fourteenth day after birth, consists of hemispherical bullæ, containing at first almost clear serous fluid. The bulla, which, like the vesicle of ordinary impetigo, is formed between the stratum corneum and the rete, soon ruptures, exposing a red, moist, glistening surface from which serum continues to ooze until it dries to form a yellowish, thin crust. Extension of the infection at the margins of the ruptured bullæ occurs, the horny layer being stripped up, thus increasing the denuded area. Confluence of adjacent lesions also takes place, and in this way large tracts of skin become deprived of their horny layer. In favourable cases extension and the formation of new bullæ gradually cease, the crusts dry up and separate, and reconstitution of the horny layer proceeds without scarring, as in impetigo contagiosa. More rarely, however, the infection continues to spread, the mucous membranes of the conjunctiva, mouth and nose are invaded, ecthymatous ulceration and abscesses may occur as complications, and the infant dies with symptoms of a general septicæmia and collapse. It would seem that a fatal result has often followed involvement of the incompletely healed umbilical

scar, the infection spreading along the recently clotted vessels and causing a pyæmia.

Distribution. The eruption may begin at almost any site, most commonly perhaps on the neck, chin, fingers or toes. It may spread widely over the trunk and flexor surfaces of the limbs, but in contradistinction to the bullous congenital syphilide, it spares the palms and soles. It is probable that the condition labelled by Ritter von Rittersheim as *dermatitis exfoliativa infantum*, and sometimes known as "Ritter's disease," was merely a severe form of pemphigus neonatorum, in which there was widespread exfoliation. Ritter described epidemics, occurring in a foundling hospital in Prague between 1878 and 1880, in which out of 274 cases, about 50 per cent. died.

Prognosis. The mortality has varied greatly in the different epidemics recorded. Of recent years it has been slight, largely no doubt owing to early isolation of infected cases and greater care in the treatment of the umbilical scar.

Ætiology. The eruption has all the characters of an acute streptococcal impetigo of the bullous type, but a number of careful independent observations tend to incriminate the *S. aureus* as the causal organism (11). *S. aureus* is not a normal habitant of clean, healthy skin, but once an active infection with this organism occurs it may be cultivated even from parts of the skin widely distant from the active lesions, and the patient is a "pyococcus-carrier." Moreover, persons who have been in close contact with such a carrier may themselves harbour the organism on their skins, without necessarily developing active lesions. Probably in most cases of pemphigus neonatorum the eruption is due to direct contact of the infant with a "pyococcus-carrier." A point of importance is that although the *S. aureus*, isolated from cases of pemphigus neonatorum, does not apparently differ in its cultural reactions from the ordinary variety obtained from boils and carbuncles, nevertheless it is characterised by a tendency to produce vesicular lesions, not only in the newly born, but also in adults who have been infected from an infant. We are thus forced to the conclusion that, although in the great majority of cases staphylococcal lesions are follicular and pustular ab initio, *S. aureus*—perhaps a special strain—is capable of producing, like the *Streptococcus pyogenes longus*, vesicular and bullous lesions. It is thus responsible for the bullous form of impetigo described by Jadassohn and for pemphigus neonatorum.

Treatment. The infant should be immediately isolated, and the greatest care taken to prevent spread of the infection either by direct or indirect contact. Unless the general condition forbids it, a daily boric or zinc sulphate (1 in 10,000) bath should be given, the skin being afterwards dried by dabbing and then powdered copiously with a boro-talc dusting powder. When the lesions have dried up, a weak mercurial ointment or paste may be used. The umbilical region should be kept scrupulously clean and smeared with the mercurial ointment. The bed-clothing and linen should be sterilised. In severe cases, with extensive exfoliation, the infant should be exposed as little as possible and kept very warm. Recovery probably depends upon the development of immunity, and it is doubtful whether treatment affects the prognosis.

MULTIPLE ABSCESES OF INFANTS

This condition, which is not a common one, is seen as a rule in marasmic children suffering from improper feeding, enteritis, bronchopneumonia, etc. It is apt to be associated with the infantile erythema of Jacquet. The abscesses begin as hard, deep nodules in the skin, particularly in situations liable to soiling, such as the buttocks and thighs, and to friction or pressure. Early lesions can be felt before they are visible, and the colour of the nodules remains unchanged until the abscess approaches the surface, when the overlying skin becomes red or bluish, and, unless previously incised, ruptures with the discharge of liquid pus.

In neglected infants ulcers or fistulæ may supervene, and secondary adenitis, with subsequent softening, may be a complication.

The nodules vary from a pea to a hen's egg in size, and the quantity of pus they contain is often astonishing. The diagnosis is easy, although the nodules have been mistaken for gummata, which are very rare in infants, and for cold tuberculous abscesses.

Ætiology. The abscesses were formerly thought to be pyæmic in nature, but it has been shown that they are due to infection with a staphylococcus (*S. aureus* or *albus*), *viâ* the sweat-ducts. The depth of the lesions is thus explained. With them may coexist small superficial intra-epidermic pustules which are formed at the orifices of the sweat-ducts.

Treatment. The most important part of the treatment is to attempt to raise the infant's resistance by attending to the underlying debilitated condition. Locally scrupulous cleanliness, the incision with a small knife of the abscesses, boric baths, and the copious use of a boro-talc powder are the only measures necessary. The infants should, if possible, be kept in bed out of doors.

SYCOSIS COCCOGENICA

By the term *sycosis* is meant a pustular folliculitis of the hairy parts ; two forms are recognised, one, *simple sycosis* or *sycosis coccogenica*, due to infection of the follicles with a staphylococcus, the other, *tinea sycosis*, due primarily to infection with a ringworm fungus, but later complicated by invasion with pyogenic organisms. The commonest sites of infection in coccogenic sycosis are the beard and moustache regions in men, but a similar folliculitis occurs on other hairy parts, such as the eyebrows, axillæ, pubis, and scalp. The lesions are follicular pustules and papules, which are pierced by the hairs. They may be discrete, but more commonly are confluent, occurring in irregular patches, or in severe cases involving the whole of the beard and moustache regions. The skin between the follicles is usually affected with a diffuse staphylococcal dermatitis (so-called "seborrhœic sycosis"). The degree of inflammation varies ; in some cases it is severe, so that the affected parts are red and swollen and covered with yellowish crusts, formed by the dried sero-purulent exudate ; in others there is no swelling, but either discrete pustules and papules, arranged singly or in confluent patches, or a diffuse scaly dermatitis dotted with yellow follicular pustules.

Contrary to what might be expected, the infection in sycosis is superficial, intra-epidermal and localised to the upper third or quarter of the follicles. Only very rarely does it spread to the deeper parts of a follicle and destroy the hair. It is for this reason that the hairs resist traction with forceps ; epilation is painful, and permanent cicatricial atrophy is rare in sycosis, except as the result of excessive radiotherapy. Sycosis begins as an attack of acute porofolliculitis, or gradually becomes established after several attacks. The essential difference between the two forms of folliculitis is that, whereas in simple porofolliculitis the epidermis is able to deal with the infection and the pustules occur singly and heal spontaneously, in sycosis the epidermis has lost its defensive power, and new pustules keep on forming in it beneath the older ones. It will be noted that the only regions affected in sycosis are those that bear large hairs, hence on the cheeks and upper lip it occurs only in males ; moreover, it is men in whom the hairs of the beard and moustache are particularly coarse that are most liable to the disease. Removal of the hairs from the follicles, either by epilation or the X-rays, leads to a temporary cessation of the pustulation, but recurrence takes place with their regrowth. It is clear, therefore, that the presence in the follicles of coarse hair is an important factor.

Morbid Anatomy. The elementary lesions of sycosis occur solely in the epidermis, and are essentially those of a porofolliculitis (*q.v.*), but they are confluent, occupy nearly all the follicles of the affected region, and are constantly

renewed. The chronicity of the affection is due to this incessant formation of new pustules, which are situated at the ostia and in the infundibula of the follicles; small miliary intra-epidermic abscesses develop beneath these pustules. Rarely the infection spreads downwards to the hair bulb, involving the whole depth of the follicle, a peribulbar abscess is produced, the hair is loosened and expelled, and the follicle sclerosed and destroyed. On extracting such a hair with forceps the epithelial sheath will be found infiltrated with pus, but this is very exceptional. The polymorphonuclear exudation is confined to the epidermis, and dermal abscesses are never found. Around the infected follicles, however, there is vascular dilatation in the dermis and infiltration of its upper portion with mononuclear cells. In cases of some months' duration plasma cells and giant cells appear, and the induration that characterises the nodular type of sycosis is due to the density of this cellular infiltration of the dermis. In long-standing cases may be seen epithelial down-growths, and a tendency to the formation of new follicles with rudimentary hairs.

Ætiology. The infecting organism is usually a *Staphylococcus aureus*, although the white and yellow varieties are sometimes responsible. The condition is never seen except in seborrhœic persons, and usually other seborrhœic manifestations, such as pityriasis, seborrhœic dermatitis, acne and boils, are or have been at times present. The most severe and resistant cases occur in those whose resistance to infection has been low from childhood, the subjects of chronic infective eczematous dermatitis of the scalp, ears and flexures, chronic blepharitis, rhinitis, and naso-pharyngeal catarrh. The condition may arise on the beard region after an attack of seborrhœic dermatitis or furunculosis, from direct infection in the barber's shop, and from the extension of the superficial staphylococcal folliculitis so common in seborrhœic persons with a stiff beard. It may also follow an attack of impetigo contagiosa, the secondarily infecting staphylococci invading the follicles. The possibility of this complication should always be borne in mind in cases of impetigo of the beard region in men. Sycosis of the moustache is nearly always secondary to an acute or chronic nasal catarrh; it may be unilateral at its commencement. As Sabouraud has pointed out, it not infrequently occurs in those who have suffered from childhood from a chronic staphylococcal blepharitis, virulent staphylococci passing down the nasal duct and invading the follicles of the upper lip when the moustache begins to grow.

Besredka's contention that resistance to staphylococcal infection is a function of the epidermis would seem to be illustrated by the special features of sycosis, the persistence of which is clearly dependent upon a loss of this defensive power, the reasons for which are not altogether understood. However (12), when an infection, as in sycosis, is limited to the epidermis, vaccines given by subcutaneous injection are useless, but when the epidermal barrier is passed and the dermis is itself infected, they may be expected to give good results. Rational treatment of a purely epidermal infection with banal organisms must obviously be designed to restore the antibacterial function of the skin to normal, and a study of those in whom sycosis occurs gives us a clue as to how this function may be lost. We can recognise two groups of cases—one occurring among the poorer classes, in which owing to unhygienic surroundings, lack of fresh air and sunlight, and a deficient dietary, the patients suffer from childhood from chronic infection of the skin and mucous membranes with pyogenic organisms, and in them the sycosis is merely a superadded complication consequent upon the adult growth of the moustache and beard; the other, occurring among the well-to-do, who develop seborrhœic manifestations owing to excess of food and drink and lack of outdoor exercise.

Treatment. Local. A consideration of the micropathology of sycosis suffices to explain why it is impossible to effect a cure by local antiseptic applications, since these cannot penetrate to the depth of the horny layer, much less to the infundibula of the follicles or the rete Malpighii. One may attempt to

limit the spread of infection by painting the surrounding skin with a 1 per cent. solution of iodine in spirit, or by the application of ointments or pastes containing sulphur, mercury, resorcin, etc., but the actual infected areas are best treated by painting them with an aqueous solution of ichthyol (25 to 75 per cent.) at night-time, which can be washed off in the morning, or with brilliant green (5 gr. to the ounce of 25 per cent. spirit). The effect of epilation has already been noted, and in chronic cases is advisable. By far the most rapid result is obtained by radiotherapy, and a single epilation dose usually produces apparent cure, but relapse is the rule when the hair regrows. Fractional doses of X-rays also have a beneficial effect, even though they do not cause the hair to fall. Epilation with forceps, though tedious and painful, has the advantage over radiotherapy that it may be continued indefinitely; it should be carried out not only on the affected area, but also beyond it to prevent extension. Local applications of ultra-violet light are undoubtedly of value, and probably act by stimulating the defensive mechanism of the skin; they may well be combined with total light baths.

General. If possible the patient should live an outdoor life, and take vigorous exercise in light clothing. Sun-bathing and the action of cool air on the skin of the whole body are more likely to effect a permanent cure than any other method of treatment. The dietary should be that advised for the seborrhœic state. Staphylococcal vaccines, given subcutaneously, are of little or no value. Injected *intradermally*, however, in doses of from 25 to 500 million their effect may be very striking, and good results have been obtained, even in long-standing cases. Besredka's staphylococcal antiviral (the filtrate of ten-day-old cultures which contain auto-inhibitory substances), applied on compresses to the affected areas at night time, is also claimed to have been successful in early cases.

SYCOSIS NUCHÆ

(*Acne Cheloid*; *Dermatitis Papillaris Capillitii*)

This condition is analogous to ordinary sycosis, and like it occurs exclusively in males who are seborrhœic. It is a perifollicular inflammation of the nucha, and is characterised by the formation of dense cheloid-like sclerosis of the connective tissue. On the affected area comedones, deep follicular pustules, and abscesses are seen. Sometimes bluish-red papillomatous vegetations arise, which bleed easily and discharge an offensive semipurulent secretion. These vegetations later become transformed into cheloid bands. Many of the hair-follicles are destroyed by the chronic inflammation, but some are spared, so that characteristic little tufts of hair are left projecting from the cheloid mass.

Ætiology. The condition, as has been said, is confined to males, many of whom suffer or have suffered from ordinary acne or sycosis. It is without doubt due to a chronic infection of the nuchal skin with a *Staphylococcus aureus*, and probably the dense nature of the connective tissue in this situation is responsible for the peculiarly indolent nature of the inflammatory process, and for the resulting cheloid-like formation.

Treatment. Apart from the general measures advised in sycosis, the only treatment that is really satisfactory is radiotherapy. Full pastille doses should be given at intervals of a month, or fractional doses at shorter intervals.

ACNE NECROTICA

(*Acne varioliformis. Acne frontalis.*)

This eruption is met with chiefly in persons over forty years of age, living a sedentary indoor life and eating to excess, but occasionally it occurs in adolescence. It is commoner in the male sex. The lesions are characteristic, both

clinically and microscopically. They commence as follicular papules, surrounded by a red halo of inflammation; at their apices develop vesiculo-pustules, which very rapidly dry up to form the characteristic crusts. These are biconvex, yellowish-brown in colour, and firmly embedded in the skin; on the scalp they are always centred by a hair; when they fall they leave pitted scars, the depth of which varies according to the severity of the case. Usually small, the lesions may occasionally attain the size of a threepenny bit, and the resulting scars are then very disfiguring. The sites of election are the forehead, along the margin of the hair, the temples, the scalp, the nose and naso-labial folds, and the midline of the back and chest. The eruption is essentially chronic, and progresses by the development of fresh crops of lesions, which are heralded by severe itching, burning, or even actual pain, the subjective symptoms being usually out of proportion to the objective signs.

Morbid Anatomy. Histologically the lesion is seen to result from necrosis at the orifice of a pilosebaceous follicle, involving the whole epidermis and a portion of the underlying dermis. This necrotic area forms the lenticular crust, in the centre of which are found the remains of the follicle, hair, and sebaceous gland. Lying in the infundibulum of the follicle are colonies of the microbacillus of acne, at the ostium and along the upper and lower borders of the crust are masses of the *Staphylococcus aureus*.

Ætiology. Acne necrotica would appear to be due to a superadded infection with a *S. aureus* of a follicle already infected with the acne bacillus. These two organisms are constantly present, and the necrotic nature of the lesions is due to the staphylococcus. The patients are always seborrhœic, and the eruption is commonest in fat, plethoric men past middle age. As with other seborrhœic conditions, an excessive carbohydrate dietary, alcoholism, and lack of outdoor exercise are important factors.

Treatment. Locally, frequent washing of the scalp and other affected areas, and the application at night time of an ointment containing sulphur and oil of cade, *e.g.* R. Olei cadini 10·0, Sulphur præcip. 1·0, Vaselinei alb. lanolini āā 10·0, or sulphur alone, will usually suffice to clear the eruption temporarily, but relapse is the rule unless the diet and mode of life be changed. Sabouraud advises total abstinence from bread, but the general treatment is that for the seborrhœic state (*q.v.*). In constantly relapsing cases an autogenous or stock staphylococcal vaccine, given intradermally as advised for sycosis, should be tried.

HIDRADENITIS

Frequently mistaken for furunculosis, this affection occurs almost exclusively in the axillæ and, more rarely, in the perinæum. The lesions consist of oval, inflammatory nodules, which are often extremely painful; they may involute without breaking down, but more commonly soften, burst and discharge a creamy pus, but, unlike a boil, no core. The inflammation is essentially indolent, and each nodule may last from ten days to a fortnight. Recurrence is very common, and in severe cases both axillæ in their entirety may be involved with multiple lesions.

Ætiology. The nodules, like those of the condition known as "multiple abscesses of infants," are due to staphylococcal infection of the sweat-glands, and not of the pilo-sebaceous follicles. The affection is commoner in women than in men, and occurs in seborrhœic persons who perspire freely. It is a not uncommon complication of generalised seborrhœic dermatitis, particularly when the axillæ are involved, or of infective eczematoid dermatitis.

Treatment. The measures already indicated for the treatment of the seborrhœic state and of staphylococcal infections should be instituted. Locally, the axillæ should be painted daily with R. Tinct. Iodi. mitis 1·0, Spirit methyl. ad 10·0, and a boro-salicylic dusting powder applied freely.

GRANULOMA PYOGENICUM

In this country two different types of lesion are referred to under this term :

(1) The condition was formerly called *Botryomycosis hominis*. It has been applied to small, pedunculated tumours of the skin similar to those which sometimes develop in horses in the wound left by castration. They were thought to be due to infection with a special fungus, the *Botryomyces*, but the mulberry-like masses, which were mistaken for parasitic elements, are really degenerated cells. The tumour varies in size from a pea to a nut. It is red in colour, round or slightly flattened vertically, and its surface is smooth or mamillated. It is not, as a rule, covered by epidermis, but rests on the dermis, from which it is separated by a groove, at the bottom of which, on drawing the tumour to one side, the pedicle can be seen. It is firm and elastic to the touch, and bleeds easily ; sometimes it is covered with a yellowish crust. The lesions are seen most commonly on the hands and fingers, but may also occur on the face, feet, legs, lips, scalp and even the tongue. Unless removed they tend to persist indefinitely. Histologically they consist of embryonic connective tissue with large numbers of newly-formed, friable capillary blood vessels, such as are seen in an angioma.

(2) A fungating warty patch, often of considerable size, resembling blastomycosis or lupus verrucosus. It begins as a pustular lesion, which spreads excentrically and develops soft vascular granulations. These later take on a verrucose appearance, and the fully developed patch is circular or irregular in shape, projects to a varying extent above the level of the surrounding skin, and is covered with crusts, between and beneath which can be seen the warty, vegetating, granulomatous surface. Pressure on the lesion causes droplets of pus to exude. The subjective symptoms are slight, and, unless treated, the course of the affection is indolent and chronic.

Ætiology. Both types of pyogenic granuloma tend to occur on exposed parts, and to complicate a preceding septic infection, particularly a suppurating abrasion or wound. On bacteriological examination a *Staphylococcus aureus* is usually obtained in pure culture, but the factors responsible for the vegetating character of the lesions are unknown. Irritation by caustics sometimes appears to provoke the appearance of the first type. It is important to distinguish the second from lupus verrucosus, blastomycosis, sporotrichosis, and trichophytosis.

Treatment. The first type of lesion should be snipped off with scissors, and the pedicle cauterised with a silver nitrate stick to prevent recurrence. The local application of ultra-violet light has also been found curative. The second type will usually yield to the constant application of antiseptic lotions, such as perchloride of mercury (1 in 3,000), or the eau d'Alibour. In some cases a full pastille dose of X-rays is advisable.

DERMATITIS INFECTIOSA ECZEMATOIDES

Under this title Engman, and later Fordyce and Sutton, have described a form of eczematoïd dermatitis, which usually follows some localised infective lesion of the skin, such as a chronic patch of varicose dermatitis, occupational eczema, furunculosis or carbuncle, wounds, chronic otorrhœa, discharging sinuses, etc. It is not uncommonly seen after an attack of scabies with secondary infection, in chronic osteomyelitis with infection of the overlying skin, and after compound fractures. The eruption, as a rule, begins as eczematous patches around the original infective lesion, and then there appear *at a distance from this* more or less sharply circumscribed circular or oval patches, most commonly situated on the arms, thighs and legs. These patches are highly characteristic, and may be seen to arise from a single vesicle or vesico-pustule on an erythematous base ; the inflammation spreads peripherally until a circinate patch is formed ; the vesicles are large, and dry up to form discrete yellowish crusts.

Ætiology. The type of inflammation of the skin which we call *eczema*

is an indication of epidermal sensitisation, and in dermatitis infectiosa eczematoides the sensitising agent is a staphylococcus, usually the *S. aureus*. Sensitisation takes place owing to the existence of some focus of staphylococcal infection in the skin. Positive cutaneous reactions to the staphylococcus are often obtained, and Sutton has pointed out that in about 25 per cent. of cases urticarial lesions may accompany the eruption, thus indicating that dermal, as well as epidermal, sensitisation has occurred. Eyre has shown that specific agglutinins to the infecting staphylococcus are often present in the blood.

Treatment. It is essential first to treat the original focus of infection, to which the sensitisation of the skin is due. When this is cured the further outbreak of eczematous patches sometimes, but not always, ceases. Desensitisation should, in persistent cases, be attempted by increasing doses of an autogenous staphylococcal vaccine. In some cases intravenous or intramuscular injections of peptone are successful. Locally the eczematous patches should be covered with a paste containing tar and ammoniated mercury, *e.g.* R. Liq. picis carbonis m. xxx to dm. i, Hydrarg. ammoniat. gr. v, Past. Zinci Comp. B.P. ad oz. i; they may be painted, previous to the application of the paste, with a 2 per cent. solution of silver nitrate in Spt. ætheris nitrosi, and in some cases a crude coal tar paste is the most effective application. Most patients who develop the condition are seborrhœic, and the administration of alkalis, as Sutton has noted, is often valuable.

ACRODERMATITIS CONTINUA

(*Dermatitis repens*)

In 1888, Radcliffe Crocker (13) described under the term *Dermatitis repens* an eruption which he defined as "a spreading dermatitis, usually following injuries, and probably neuritic, commencing almost exclusively in the upper extremities."

Symptoms. Crocker's description of the localised eruption was as follows:—

"In all cases in which inquiry has been made, an injury, often a trivial one, has been the exciting cause. Vesicles or a bulla have appeared at the site of the injury, and these have ruptured, and the elevated epidermis has been thrown off, leaving a bright red surface, oozing a clear or slightly turbid fluid. The border of the denuded area is bounded by a collar of the epidermis, which is raised up by subjacent fluid, clear or turbid, and is sodden and irregular. Sometimes extension takes place by the continued detachment of the epidermis by further exudation, or there may be fresh vesicles or small bullæ just beyond the border, which break down and add a newly-denuded area to the original adjacent one."

One of the most characteristic features of the condition is involvement of the nails, which are affected exactly as in ordinary whitlow. The eruption may be confined to one hand or foot, but both hands or all four extremities are involved in some cases. The subjective symptoms are moderate local itching, and sometimes pain, which may be intense. There is seldom any secondary lymphangitis, and constitutional disturbance is slight or nil. The course is essentially slow and chronic, and at one time the disease was considered incurable. Finally there may be shrinking of the affected digits, with disappearance of the nails, and their reduction to little conical and sclerosed stumps. X-ray examination may reveal, even in cases of moderate severity, osteitis and absorption of the underlying bones, particularly of the terminal phalanges.

In the generalised form of the disease, apart from the characteristic eruption of *Dermatitis repens* on the hands and feet and the involvement of the nails, pustular lesions appear on the trunk, limbs and scalp. These extend peripherally, drying up in their central portions to form crusted patches often of considerable size. The crusts may resemble at first sight those of chronic psoriasis, but they consist of the exfoliated horny layer and dried sero-pus, and beneath them liquid

pus is exuded from a moist oozing surface. The oral, conjunctival and urethral mucous membranes may all be involved in generalised cases, as in a male patient observed by the writer. The tongue is affected by a superficial glossitis, with white patches due to the formation of a diphtheroid membrane; recurrent acute attacks, coinciding with exacerbations of the eruption on the skin, occur, and may lead to furrowing as in *lingua plicata*.

Morbid Anatomy. The essential lesion is caused by an infiltration of the upper Malpighian layers by polymorphonuclear leucocytes, with the result that an abscess is formed just beneath the horny layer, extending downwards to the summit of the underlying papilla. Resolution takes place by the desiccation of the abscess, and its inclusion and exfoliation by parakeratotic horny cells. Histologically, therefore, *Acrodermatitis continua* may be compared to psoriasis, but in the latter the polymorphonuclear infiltration does not form true abscesses, except in the pustular variety of the disease.

Ætiology. From the investigation both of the localised and generalised forms of the disease, it would appear that the primary cause is an infection with *S. aureus* (14).

Prognosis. Both forms of the eruption are essentially chronic and resistant to treatment. In Stowers's case the condition lasted forty-five years and persisted till death. In Strandberg's three cases it had been present fourteen, thirteen and five years respectively. In one observed by the writer the duration was nine months from the onset to the final recovery; in another the patient had been affected for twelve years with periodical remissions. The view, however, that the disease is incurable is erroneous.

Treatment. The methods of treatment that have been successfully employed by the writer are: (1) Autogenous vaccine therapy with the staphylococcus isolated, persisted with over a long period in suitable increasing doses. (2) The local application to the lesions of an autogenous antiviral, and various antiseptics, combined with baths to which cyllin or monsol is added. (3) Total ultra-violet light baths, and as far as possible an out-of-door life. It is probable that *intra-dermal* rather than subcutaneous injections of the vaccine would, as in staphylococcal syphilis, be more effective.

THE SEBORRHŒIC STATE AND ASSOCIATED INFECTIONS

Ætiology. As already pointed out, there are three micro-organisms that are so commonly present in the skin of civilised man that they may be considered as its normal inhabitants, viz. the pityrosporon of Malassez, the microbacillus of acne, and the *S. albus*. On absolutely healthy skin they are present merely as saprophytes; when, however, conditions are favourable, they take on active growth, and produce reactions in the skin, which vary in nature according to the organism responsible. It is important to note that, when it occurs, active growth of all three organisms usually takes place simultaneously, although one or other may predominate; consequently it may be concluded that the conditions that favour the changes from saprophytism to parasitism are the same for all three.

The most important predisposing factor responsible for this change is the morbid state of the skin known as *Seborrhœa*, by which is meant an excessive and altered secretion from the sebaceous glands, and a change in the composition of the fat in the horny layer. The normal fat of the skin is composed of various neutral fats, mixed with fatty acids, which are in combination, not with the trihydroxy-alcohol glycerol, but with the monatomic alcohol cholesterol. These cholesterol fats are not easily decomposed by bacterial growth, and are not a suitable culture medium. It is probable that the *essential* factor that favours the active growth of the above three organisms, and consequently the various

seborrhœic infections, is the alteration in the secretion and composition of the cutaneous fat that obtains in seborrhœa, but the factors predisposing to this are complex. They may be briefly reviewed as follows :—

Heredity and Predisposition. There is unquestionably in many cases an hereditary tendency to seborrhœa and its complications. Seborrhœic families are common, and conversely some appear to be comparatively immune. Heredity is certainly an important factor in calvities—the so-called seborrhœic alopecia of men. There is also a congenital predisposition to the seborrhœic state, which may sometimes be detected in infancy.

Age and Sexual Evolution. In a person with a congenital predisposition the various seborrhœic manifestations follow a certain evolution in relationship to age. The true milk-crust is by many considered the earliest sign of the seborrhœic tendency. The infant's head early becomes infected with the pityrosporon, which may cause the seborrhœic variety of infantile eczema. This infection persists as dry dandruff of the scalp until puberty, at which time the sebaceous glands awaken into activity. The scalp and face become greasy, and the simple infection of the former with the pityrosporon is complicated by the active growth of the *S. albus*, resulting in the so-called *Pityriasis steatoides*. The acne bacillus now grows actively in the infundibula of the pilo-sebaceous follicles, and the comedones and pustules of juvenile acne appear. This continues until the age of twenty-five or longer, and is often associated with or succeeded by seborrhœic dermatitis. At about eighteen years, or later, begins the loss of hair on the vertex and temples, which progresses towards the calvities of early middle life. In the third or fourth decade the acne of adolescence is succeeded by rosacea, which in women is often accompanied by hypertrichosis; at this time, too, appear the so-called seborrhœic warts, which persist till death.

Influence of Sex. There is an intimate relationship between the pilo-sebaceous system and the sexual glands, and also between the growth of the hair and the activity of the sebaceous glands. Virility tends to a loss of hair on the scalp, with its increased luxuriance on the face and body: feminism to a converse distribution.

Eunuchs never develop calvities, and women at the time of the menopause are apt to suffer a considerable loss of hair and to develop a rudimentary beard and moustache. Seborrhœa in both sexes is usually associated with a tendency to a fall of hair on the scalp and growth of coarse hair on the face and body. In cases of suprarenal tumour in women, apart from other signs of virilism, the pilo-sebaceous system undergoes changes characteristic of the male, and the growth of a beard and moustache is accompanied by calvities.

Diet and Mode of Life. If it is admitted that the seborrhœic state is associated with a faulty metabolism of fat and fat-forming foods, it is obvious that diet, or rather the correlation between diet and the expenditure of physical energy, is a factor of great importance. Even those who have no inborn predisposition, and who, while living the active outdoor life of adolescence and early adult life, remain free from seborrhœic symptoms, may develop them for the first time when they abandon their games, adopt a sedentary occupation, and continue to eat as much or more than previously. Clinical observations show clearly that, as regards diet, carbohydrates, particularly cane sugar and soft starchy foods, which are liable to undergo bacterial fermentation with fatty-acid production, certain fats, and alcohol, are, when taken in excess, most likely to provoke seborrhœa and its complications. Sabouraud has emphasised the beneficial effect upon certain seborrhœic eruptions, *e.g.* acne necrotica, rosacea, of complete abstention from ordinary bread, which is often consumed mechanically at meals otherwise adequate or excessive. Other soft farinaceous foods, particularly if cooked with milk, are equally harmful.

With regard to fats, it has been shown that the sebaceous secretion may abnormally have the same chemical characteristics as the fat ingested, and that this is due to the ability of the sebaceous glands to fix directly fatty particles

circulating in the blood. This extraneous fat, like other *depôt* fat, is coloured by sudan-red given with food, whereas the normal sebum, which is elaborated from the fatty-acids in the blood by a process of cellular activity, *i.e.* is a true secretion, is not. The normal function, therefore, of the sebaceous glands is adipogenesis, the manufactured fat having a special composition of its own; under certain conditions, *e.g.* in animals after hyperalimentation, they take on the function of adipopexy, in which case the fat taken up directly from the blood may have the characters of that ingested. Presumably, therefore, the composition of the sebum may be altered by an excessive intake of fat or fat-forming foods, or by the ingestion of special forms of fat. Pig fat, cheese, and chocolate in some cases of acne invariably aggravate the eruption; milk fat also, which is particularly liable to bacterial decomposition, when taken in excess appears to increase a tendency to seborrhœa. Alcoholic liquors have a similar effect, partly, no doubt, because alcohol is a fat-sparer and a vasodilator, and partly owing to the sugar they contain. It is clear, however, that the question of diet must be considered in relationship to the amount of exercise taken, and the mode of life (see section on treatment).

Apart from these factors, it should be noted that the secretion of sebum is, like that of the sweat, saliva, and tears, under the control of the autonomic nervous system. In encephalitis lethargica, and in other cases manifesting the Parkinsonian syndrome, excessive secretion of sebum, giving rise to the "seborrhœic facies," usually associated with sialorrhœa, may be a striking symptom, and would appear to depend upon lesions in the neighbourhood of the third ventricle involving vegetative nerve centres (15).

The Seborrhœic Triad of Organism. The three organisms, to the active growth of which in the skin the seborrhœic state predisposes, are, as has been said, the pityrosporon of Malassez, the acne bacillus, and the *Staphylococcus albus*. The pityrosporon (sometimes called the "spore of Malassez, and, erroneously, the "bottle-bacillus") is now generally accepted as the cause of simple dandruff, or *pityriasis simplex*, in the horny scales of which it is found in a state of active growth. It is a pleomorphic organism, and simple spherical or sausage-shaped forms are seen mingled with the commoner and characteristic flask-shaped variety. It was pointed out (16) that, whereas this organism is found alone in pityriasis simplex, growing between the superficial layers of the stratum corneum exactly as does the *Microsporon furfur* in pityriasis or tinea versicolor, in pityriasis steatoides, and in the group of eruptions variously known as seborrhœic dermatitis or eczema, seborrhœoides, *eczématides* (Darier), *S. albus* is also seen with it in a state of active multiplication. It was therefore held that these conditions were due to a symbiotic infection with both organisms. Attempts to obtain the pityrosporon on artificial media in pure culture have generally failed, but Garner has claimed to have succeeded, using maltose agar and acid glycerine agar. MacLeod and Dowling (17) determined the sugar-reactions of his cultures, and performed inoculation experiments with it. They conclude that the organism is one of the fungi imperfecti, belongs to the class *Oösporaceæ*, and is nearly related to the monilia group. By inoculation of cultures they were able to produce typical figurate seborrhœic dermatitis, indistinguishable both in evolution and appearances from the natural eruption. Inoculation on normal non-seborrhœic skins produced a group of follicular papules within twenty-four hours, which lasted about ten days and then disappeared; in some seborrhœic subjects, particularly those with active seborrhœic dermatitis present, a more acute reaction developed, and a widespread figurate patch sometimes resulted. They also found that intra-dermal injections of the organism in persons with seborrhœic dermatitis produced both local and focal reactions. They therefore regard seborrhœic dermatitis as being primarily due to the pityrosporon, and the *S. albus* as a secondary invader. The fact remains, however, that the latter is always found in a state of active growth in this condition.

The acne bacillus (or microbacillus of seborrhœa) in seborrhœic persons flourishes in the infundibulum or upper third of the pilosebaceous follicle, and if the so-called "seborrhœic cocoon" be expressed from the follicle, squeezed flat on a slide, and suitably stained, myriads of acne bacilli will be seen obviously in a state of active growth. As a result of infection of the follicles with this organism there may arise in certain situations the polymorphic lesions of the common acne juvenilis—comedones or "blackheads," acne papules, pustules, etc. Sabouraud maintains that the true acne pustule is due to the acne bacillus, and not to a secondary invasion with *S. albus*, although staphylococcal lesions may be and often are present in acne. This view has been recently confirmed by work on the staphylococci in acne vulgaris (18).

The characters and rôle of *S. albus* have already been referred to (p. 841).

It should be noted that each of these three organisms has its own localisation or site of election in the skin, and each, when it takes on active growth, excites a special type of cell-response to invasion. Thus the pityrosporon, like a ringworm fungus, e.g. the microsporon furfur, grows in between the layers of the stratum corneum, which hypertrophies, and is shed in visible flakes or pellicules ("dandruff" or "scurf"), such exfoliation, no doubt, being an attempt to cast off the parasite; on the scalp and other hairy parts, the pityrosporon, like certain ringworm fungi, may excite little or no inflammatory response in the cutis, but on the glabrous skin both it and a ringworm fungus provoke definite clinical and histological signs of inflammation. The acne bacillus flourishes in myriads in the infundibular portion of the pilosebaceous follicles, and there may, like the pityrosporon, provoke both a non-inflammatory and inflammatory defence-reaction—viz., the comedo and the acne pustule. The comedo may be regarded as a cyst, formed of horny cells, and designed to enclose the mass of acne bacilli like a foreign body. The true acne pustule represents the inflammatory defence-reaction to the bacillus, although it has commonly been held to result from secondary infection with a *Staphylococcus albus*. Sabouraud has clearly shown that the acne bacillus alone is responsible, and he points out that the leucocytic reaction is denser than in staphylococcal infection, producing thick caseous pus, unlike the fluid creamy "laudable pus" of the latter. The site of election for staphylococci is the ostium of the pilosebaceous-follicle, and the migration of polymorphonuclear leucocytes is the normal defence-reaction in response to staphylococcal infection.

Symptoms. *Cutaneous.* The skin of a person in perfect health, who lives an athletic outdoor life, is smooth, supple and clear. The horny layer is thin and translucent, and is cast off in invisible flakes, the pilosebaceous orifices are hardly visible, and the secretion of sebum and sweat (except in heat, strong sunlight and after exercise) is imperceptible; the hair is sleek and not greasy, and there is no evidence whatever in the skin of active bacterial growth.

In the seborrhœic person, on the other hand, the skin as a whole appears thickened, coarse and dirty, particularly in dark-complexioned persons; the horny layer is improperly formed, and hypertrophied; the pilosebaceous orifices are enlarged and patulous, and either exude visible droplets of oily sebum or are filled with solid plugs—the so-called seborrhœic cocoons—containing countless acne bacilli; there is often visible hyperidrosis in certain situations; the scalp after puberty is greasy, covered with adherent dandruff, which swarms with the pityrosporon and the *S. albus*, and the hair dank and lifeless. To this picture must be added the infective complications—the comedones, pustules, and nodules of acne, the various forms of seborrhœic dermatitis, the superficial pustules due to the *S. albus*, the deeper folliculitis of sycosis and boils due to the *S. aureus*. In middle life rosacea, which sooner or later becomes complicated by a super-added infection of the flushed area with the seborrhœic organisms, is common. It should be noted, however, that clinically can be recognised two types of seborrhœic person. The one, usually fair-complexioned, is flushed, robust,

active, and in later life often plethoric ; the other, usually dark, is pallid, coarse-skinned, pigmented and indolent. In the latter a history of tuberculosis of glands, bone, or peritoneum in childhood is often obtained, and many develop phthisis in adult life ; it is in them that the deep nodular form of acne, with deep and often cheloidal scarring, is most commonly seen.

Mucous Membranes. In the first type of seborrhœic the vermilion borders of the lips are usually bright red, and covered with a yellowish superficial crust ; the tongue is firm and red, and the papillæ prominent ; gingivitis, representing doubtless the same lowered resistance to infection that characterises the skin, is common, and the earlier the onset of the seborrhœic state, the sooner does it occur. In the other type of seborrhœic person, the lips may be pale or bluish, the tongue pale and indented, and its papillæ hardly visible. Accompanying the gingivitis there is often a marked tendency to dental caries.

Chronic nasopharyngeal catarrh, with frequent exacerbations, is almost invariably present in severe cases of the seborrhœic state. It was a striking symptom among those met with in France during the war. In chronic seborrhœics, with symptoms dating from childhood, this catarrh is usually associated with the adenoid facies and marked hypertrophy of the lymphoid tissue ; on the other hand, it may develop as an entirely new symptom, in conjunction with infection of the skin, in those who became seborrhœic as a result of adopting a sedentary existence in middle life.

The Digestive System. True flatulence, distinct from aerophagy, is a common symptom, due apparently to fermentation of carbohydrates, since it is usually relieved by exclusion of soft carbohydrate foods from the dietary.

The Urine in the seborrhœic state has been studied by several observers. The alkaline tolerance is, as a rule, markedly raised, so that very large doses of alkali may be required to render the urine alkaline. In some cases, usually of long standing, the ammonia-ratio and acid-ratio are high. Observations on the hydrogen ion concentration of the urine in the seborrhœic state have shown that the *pH* value in normal controls (from which seborrhœic persons were carefully excluded) varied from 6.4 to 6.8, whereas in patients with seborrhœic manifestations it varied from 4.8 to 5.8. Striking benefit accrues in these cases from the administration of alkali in sufficient quantity to restore the *pH* value to normal. A point of great interest is that the urine of a patient, even with severe seborrhœic manifestations, may be found to be slightly acid or even neutral, but that, when alkali is administered, its acidity increases progressively up to a certain point before becoming alkaline.

Treatment. The treatment of seborrhœic patients naturally varies according to the individual case, but certain general principles may be outlined. The diet must be regulated according to the climatic conditions and the amount of physical exercise taken. Starchy foods must be taken in a form that requires thorough mastication, and ordinary white bread, milk puddings, and other soft farinaceous foods should be forbidden. Concentrated sweetstuffs, particularly cane-sugar and chocolate, pig-fat, excess of milk-fat, alcoholic liquors, and in some cases cheese, usually aggravate seborrhœic conditions, particularly in those living a sedentary life. Raw and cooked fruits and vegetables, a moderate amount of meat, fish, eggs, milk and butter, together with crisp farinaceous foods, should form the staple dietary.

Clothing and Exercise. Excessive clothing is probably an important factor predisposing to the seborrhœic state, since it robs the skin of its natural stimulation by cool air, which activates the thyroid-adrenal-sympathetic system ; it also undoubtedly favours the growth of the seborrhœic organisms. The effect of total air and sun baths upon seborrhœic skins is very striking. The patient should be gradually trained to accustom himself to light porous clothing, and should, if possible, take vigorous outdoor exercise regularly in running costume.

Bathing. A daily hot bath, followed by cold douching, is advisable, and in severe cases hot sulphur baths taken at bedtime, at first every night, and later twice a week, may be ordered. When Spa treatment is available, alternate hot and cold douching ("Scotch douche") is of great value.

Alkalies. In those with increased urinary acidity an initial course of alkaline saline aperients should be given, and later a single early morning dose of alkali in a tumbler of water taken as a routine.

PITYRIASIS SIMPLEX

The term *pityriasis* has, unfortunately, been applied to several distinct affections of the skin. Derived from *πίτυρον*, bran, it merely signifies scaliness. *Pityriasis versicolor* is due to infection of the horny layer with a fungus, the *microsporon furfur*. *P. rosea* is a specific disease due to infection with an organism hitherto undiscovered; *P. rubra pilaris* is also a specific entity of unknown causation, and *P. rubra* is an erythrodermia.

Pityriasis simplex is a non-inflammatory, desquamative affection of the horny layer, commonly known as *dandruff* or *scurf*. In its simple form it affects chiefly the hairy regions, particularly the scalp (*P. capitis*), but, as has been pointed out, the causal organism is concerned with staphylococci in the production of the inflammatory condition known as seborrhœic dermatitis (*P. circinata*). The earliest stages of the affection are seen in young children, on whose scalps it begins, usually on the vertex, as little patches of dry scurf around the hair follicles. It gradually spreads as circular scaly areas, not unlike ringworm, until it becomes diffuse. From about the age of puberty onwards, when there is likely to be concomitant seborrhœa, the scales become greasy.

The condition is due to infection of the horny layer with the pityrosporon, which has already been described. There is no doubt that infection with this organism is spread by direct and indirect contact. When it occurs in babies, in whom pityriasis simplex of the scalp may be the starting point of one form of "infantile eczema," examination of the scalp of the mother or nurse will usually reveal a heavy infection, and the indiscriminate interchange of hair-brushes is doubtless a potent cause of indirect spread.

Treatment. The general treatment of the seborrhœic state (*q.v.*) is indicated, as it is extremely difficult to eradicate the infection by local measures alone. The scalp should be washed frequently, once a week in women, twice or oftener in men. At the beginning of treatment, soap spirit (spiritus saponatus, B.P.C.), or ether soap may be employed, but they should not be persisted with. Certain proprietary shampoos, containing tar, are the best and pleasantest for regular use. In mild cases the thorough daily application of a hair-lotion is sufficient, *e.g.* R. Resorcin, Acidi salicylici ãã gr. x; Hydrarg. perchloridi gr. 1/6; Ol. lavand. m. ii (Ol. ricini q.s.); Acetoni dm. i; Spirit vini meth. indus. ad oz. i, the resorcin being omitted in persons with grey or fair hair. The lotion may be shaken on to the scalp through a sprinkler-cork and then well brushed in, or applied with a spray. In severe cases, particularly if there is much seborrhœa, the additional use of a pomade is essential, *e.g.* R. Sulphur præcip., Acidi salicylici ãã gr. xx; Vaseline alb. dm. ii; Ol. cocois nuciferæ ad oz. i; Perfume q.s.; this should be thoroughly rubbed into the scalp on the nights previous to shampooing, and the above lotion (without the perchloride of mercury) used daily. It cannot be too strongly emphasised that the popular idea that the scalp should be washed only occasionally is erroneous, and is responsible very largely for the prevalence of dandruff. Provided that strongly alkaline and spirituous shampoos (which render the hair brittle, and in women, combined with the deleterious action of dyes and waving, produce the condition known as trichorrexia nodosa) are not employed, the head may be washed as often as desired.

COMEDO

(Blackhead)

The *comedo* is one of the lesions of *acne vulgaris* (*q.v.*). It is a small, horny, cocoon-like mass, embedded in the mouth of a pilo-sebaceous follicle, and consists of concentric sheaths of horny cells, surrounding a partitioned cavity, in which lie masses of the *acne bacillus*, inspissated sebum, and the *débris* of a dead lanugo hair. The summit of the comedo is coloured dark-brown or black, not owing to adherent dirt, but to an oxidation product of keratin (ultra-marine); the lower part of the comedo is of a yellow colour. Sometimes "double" or "multiple comedones" are seen, *i.e.* two or more closely approximated comedones communicating at the base. The comedo is a retention cyst, and is due to hyperkeratosis at the mouth of a follicle, provoked doubtless by the irritation, mechanical or toxic, of the *acne bacilli* growing in the infundibulum. *The acne bacillus may, therefore, be considered as the cause of the comedo*, and the essential predisposing factor to the formation of true comedones is seborrhœa, which favours the active growth of this bacillus.

Apart, however, from the comedones of ordinary acne, various external irritants are capable of inducing comedo-formation, which may be followed by the development of pustules. The commonest of these is camphorated oil, which gives rise to the so-called "grouped comedo" of infants and children, whose chests have been assiduously rubbed for bronchitis. The suppuration in camphorated oil acne may be severe and lead to extensive scarring. Turpentine liniment sometimes produces the same condition, and in adults various tars, particularly oil of cade, and chlorine vapours may respectively be responsible ("tar-acne," "chlor-acne").

The **Treatment** of comedo is dealt with under *Acne vulgaris*.

ACNE VULGARIS

The term *acne* (according to Littré, altered by a copyist from ἀκμή, a point) has been applied, since Willan and Bateman first introduced it, to a number of distinct eruptions in which the pilo-sebaceous follicles are affected. It is now less widely used, being as a rule reserved, apart from *acne necrotica seu varioliformis*, for the common disease *acne vulgaris*—polymorphic or juvenile acne.

The epithet "polymorphic" indicates that in acne there is not a single characteristic lesion, but rather a number of different forms of eruptive elements, some of which predominate in one case, others in another. The essential predisposing factor in the development of acne is seborrhœa, and the earliest lesion is usually the *comedo* (*q.v.*), a retention cyst, the formation of which is provoked by the active growth of the *acne bacillus* in the pilo-sebaceous follicle. In some cases comedones in large numbers are present alone—*acne punctata*; in others reddish papules, usually formed around comedones, occur intermingled with simple comedones—*acne papulosa*; in others, again, the infection is more acute, the papules are bright red and acuminate, suppuration takes place at their summits, and the pus produced either exudes or dries up to form crusts, under which the papule involutes, leaving a minute scar—*acne pustulosa*; in the more severe cases large, indurated, deep-seated nodules are seen, some of which undergo a slow transformation into indolent pustules, from which a quantity of pus may be evacuated, and which on healing leave scars of considerable size and depth—*acne indurata*. Sometimes bluish-red, fluctuating abscesses are formed, which may involve the hypoderm. The so-called "butyric cysts" result from degeneration of large comedones, and contain a semi-fluid, cheesy substance, having a peculiarly nauseous smell. Mucoid cysts, due to cystic degeneration of long obstructed sebaceous glands, are more rarely seen.

As has been indicated, these different types of lesions coexist in the same patient, and all degrees of severity are met with, from a few comedones and occasional papulo-pustules to the worst form of acne indurata with large, painful nodules and abscesses, and extensive deep scarring. The distribution of acne is more or less constant, the eruption occurring almost exclusively on the face and back, less commonly on the front of the chest and over the deltoids; on the back, it involves chiefly the scapular regions and only rarely descends below the waist line.

Ætiology. The various lesions which together constitute acne vulgaris occur exclusively in seborrhœic subjects, in whose sebaceous follicles the acne bacillus grows in profusion. The disease usually first makes its appearance at about the age of puberty, when there is a great increase in the development and activity of the sebaceous glands. It may, however, occur in mild form several years before puberty. It reaches its acme of severity, as a rule, between the ages of sixteen and twenty-five, and then tends to decline, being succeeded by other manifestations of the seborrhœic state, such as calvities, furunculosis, sycosis, and seborrhœic dermatitis. In some cases, however, it may persist till late in middle life, and it is by no means uncommon to find comedones and acne papulo-pustules even in the aged. Apart from the influence of sexual maturity, the predisposing causes of acne are those of the seborrhœic state, and of particular importance are an *unsuitable dietary*, above all an excess of sweet and starchy foods and certain forms of fat (as Kenneth Wills has emphasised, pig-fat is especially injurious), *lack of fresh air, sunshine and exercise*, and *chronic constipation* with intestinal toxæmia. The worst examples of the disease are usually seen in thick-skinned persons of the scrofulous type, with the symptoms and signs of intestinal autointoxication. Many of such patients have suffered from tuberculosis of glands, peritoneum, bones or joints, and it is in these that deep scarring is most likely to occur.

Treatment. *Internal.* The internal treatment of acne vulgaris must depend on the symptoms presented by each individual patient. Thus in some cases there is anæmia, hypochlorhydria, chronic constipation, and an excess of indican in the urine; for these, morning saline aperients, pills containing iron and aloes, and dilute hydrochloric acid in doses of 20 to 40 minims after meals are indicated. In full-blooded patients, on the other hand, an alkaline mixture containing sodium bicarbonate, potassium citrate, and magnesia taken before meals is often beneficial. As regards the diet, it is usually important to restrict the amount of carbohydrate and fat, and sweets, cakes, pastries, puddings, jam and marmalade, pig-fat, chocolate, and cheese should be forbidden altogether; plenty of fresh fruit and green vegetables, and lean meat, fish, and poultry should be taken. Avoidance of excess of tea and coffee is also essential, and, whereas beer and stout in moderation are probably beneficial, wines and spirits certainly do harm. Vaccine therapy in acne is not so successful as in furunculosis, but may be of value in the pustular form. An active preparation of yeast, calcium sulphide gr. i, t.d.s., p.c., or collosol sulphur dm. ii, t.d.s., p.c., ex aqua, are worthy of trial. In certain cases with thick, sluggish skins and a feeble peripheral circulation thyroid is of very great value, and in females with irregular or scanty menstruation an active ovarian preparation should be tried.

Local. The object of the local treatment of acne vulgaris is to render the skin dry by reducing the activity of the sebaceous glands. If this be done, the micro-organisms responsible for the lesions will tend to lose their virulence and to die out. By far the most effectual method of accomplishing this object is by means of the X-rays, given preferably in fractional doses. Their employment, of course, requires great care, as over-dosage will lead to permanent telangiectatic atrophy of the skin. Next to the use of X-rays the quickest method is to produce exfoliation of the skin of the affected parts by means of strong pastes containing resorcin and sulphur, e.g. R. Resorcin, Camphor, aa 10·0, Sapo. moll. virid. 15·0, Sulph. præcip. 30·0, Cretæ præpt. 5·0, Paraff. moll. flav. 10·0, Adipis. lan.

anhyd. 20·0. The paste should be applied at night-time only, unless the patient can remain indoors; after a few days the skin will become red and sore, and will begin to peel; a soothing lotion or cream may then be substituted until exfoliation is complete, when the procedure may be repeated. By the persistent use of this method of exfoliation excellent results are obtainable even in the worst cases, and it is of great value in the treatment of severe acne of the back. Milder measures consist in applying lotions and powders or a weaker paste containing sulphur, resorcin, salicylic acid, or mercury. One of the following lotions may be applied thoroughly twice daily, after washing with a soap containing sulphur and salicylic acid (2 to 10 per cent. of each) and expressing the comedones and pustules: (1) R Potass. sulphidi ʒj, Zinc sulph. ʒj, Aq. rosæ ad ʒiv; (2) R Resorcin gr. x to xx, Boracis purif. gr. x, Zinc oxid., Calaminæ, āā gr. xv, Glycerini Mxx, Eau de Cologne Mxxx, Aq. calcis ad ʒj. The thorough application of a medicated soap containing sulphur and salicylic acid, the lather being allowed to remain on for several minutes, may alone be sufficient to cure mild cases. A suitable face powder consists of equal parts of talc and zinc oxide containing from 2 to 5 per cent. of sulphur. For the successful treatment of acne it is essential that the rules for diet laid down should be rigorously adhered to, that the patient should have plenty of daily exercise out of doors, that constipation should be avoided, and that the skin be kept dry and comedones and pustules systematically evacuated. Seborrhœa and pityriasis of the scalp, which almost constantly accompany acne, must be treated by frequent shampooing and the use of a hair lotion containing hydrarg. perchlor., salicylic acid and (except in fair- or grey-haired persons) resorcin.

Heliotherapy or total ultra-violet light baths give more permanent results, if persisted with in suitable dosage, than any other form of local treatment.

SEBORRHŒIC DERMATITIS

The term "seborrhœic dermatitis" includes a group of eruptions which have received a variety of names from different observers; for example, *lichen circumscriptus* (Willan and Bateman), *lichen annulatus serpiginosus* (Erasmus Wilson), *pityriasis circinata* (Bazin), *seborrhœa corporis* (Duhring), *eczema seborrhœicum* (Unna), *seborrhœoides* (Audry, Brocq), "flannel-rash," etc. Darier has proposed for them the term "*eczématides*," thus indicating their close clinical and histological relationship to eczema.

It is possible to recognise three main types of seborrhœic dermatitis (19): (1) The figurate type (*pityriasis circinata*, figurate medio-thoracic dermatosis of Brocq, *seborrhœa corporis* of Duhring, *pityriasis steutoides* of Sabouraud, "flannel-rash"); (2) the pityriasiform type; (3) the psoriasiform type. But it must be admitted that these distinctions are artificial, since they depend partly on the particular site involved, and they may all co-exist in the same patient.

1. *The Figurate Type.* This is seen most typically in the presternal and interseapular regions, whence it may spread laterally, and on the scalp, from which it may extend to the forehead (*corona seborrhœica*), the temples, and behind the ears. Its evolution can best be studied on the trunk. It will be observed that the inflammatory process begins at the mouths of the pilo-sebaceous follicles, so that the eruption is primarily follicular; the interfollicular areas are then involved, with the formation of petaloid patches, which by coalescence become figurate. These patches are of a pinkish or bright red colour at the spreading margins, which are slightly raised, yellowish or fawn-coloured in the centre. They are covered with greasy scales. The eruption may cause considerable itching, or may pass unnoticed and be present for years. It is very common in seborrhœic persons, particularly in those who wear flannel next the skin or excessive underclothing, and often co-exists with other seborrhœic eruptions, such as acne rosacea, sycosis, furunculosis, etc.

2. *The Pityriasiform Type.* This type represents a more diffuse form of seborrhœic inflammation of the skin. It occurs as oval, round, or irregular patches, slightly scaly, dry or greasy, according to their situation, and pink or pinkish-yellow in colour. They occur on and around the scalp, the neck, the upper portion of the trunk, and in the joint flexures, such as the axillæ, antecubital fossæ, popliteal spaces, and groins, and in the inter-natal cleft. They may also be present on the extensor surfaces of the limbs in persons with dry skins, the vulnerability of the horny layer doubtless favouring infection. Sometimes acute outbreaks of this form of seborrhœic dermatitis occur on the trunk, and the eruption may closely resemble pityriasis rosea, but the presence of the "bottle bacillus" in a state of active growth in the scales of the former suffices to distinguish between them. Secondary eczematization may take place, particularly on the scalp, ears, neck, and joint-flexures, so that the eruption becomes red, vesicular and moist from serous exudation.

3. *The Psoriasiform Type.* In this form the inflammation is deeper and more intense than in the preceding varieties. The patches are more infiltrated, of a darker red, and covered with thicker more or less adherent scales. They may resemble psoriasis very closely; in fact, in some cases it may be impossible to make a differential diagnosis without a careful microscopical examination. The eruption may occur as a single chronic patch, or may extend widely and form confluent areas of considerable size. Itching is, as a rule, a prominent symptom, and may be intense; from constant scratching and rubbing lichenification may result.

Morbid Anatomy. Although the different types of seborrhœic dermatitis vary considerably in their histological appearances, the essential lesions are much the same, and consist of small areas of *spongiosis*, *parakeratosis*, *crusts* formed by dried serum enclosing leucocytes, *acanthosis*, and œdema with perivascular cell-infiltration of the dermis. The histological changes, therefore, are of the eczematoid type, but the spongiosis is less marked, and both it and the parakeratosis are more discrete than in true eczema. The psoriasiform variety of seborrhœic dermatitis simulates psoriasis histologically as well as clinically, but researches (20) have shown that the histological differences are such that the two can be distinguished with certainty. The more important are that in the former the superficial layers consist not only of nucleated horny cells, but also of the crusts above referred to; the parakeratosis is often discontinuous; in the papillary body of the epidermis are found small areas of spongiosis, enclosing mononuclear leucocytes, and not polymorphonuclears as in psoriasis. It is these areas that become the crusts when they reach the stratum corneum. By special staining methods it can also be demonstrated that, whereas the lesions of psoriasis are remarkably amicrobial, those of seborrhœic dermatitis reveal very active microbial growth.

Ætiology. Seborrhœic dermatitis may be regarded as a diffuse catarrh of the skin due to microbial infection—in other words, an infective epidermo-dermatitis. It is characterised by the presence in the lesions of the pityrosporon and staphylococci in a state of active growth. It thus differs essentially from psoriasis, and from pityriasis rosea, in which the pityrosporon is absent. Dowling considers that all forms of seborrhœic dermatitis are primarily due to infection with the pityrosporon, which may be true, but it is probable that the differences that characterise the clinical varieties of the eruption depend chiefly on the type and virulence of the infecting staphylococcus. The seborrhœic state is the principal predisposing factor to the active growth of these organisms, and, as has been suggested, it is probably the alteration in the composition of the fat of the horny layer and sebaceous glands that favour their growth; for this reason the distribution of seborrhœic dermatitis usually corresponds to the areas in which the sebaceous glands are largest and most active. Needless to say, lack of personal cleanliness and the wearing of excessive clothing are additional predisposing causes.

Treatment. The internal treatment is that of the seborrhœic state, and the local measures to be adopted will depend on the type and severity of the inflammatory process. The figurate variety, that is seen so frequently on the back and chest, is rapidly cured by applications of sulphur, *e.g.* R Sulphur præcip. gr. x to xx, Resorcin gr. x, Past. Zinci Comp. B.P.C. ad oz. i. For the diffuse pityriasiform patches, which occur chiefly in the joint-flexures, behind the ears, and on the neck, sulphur is apt to be too irritating, and ichthyol and tar in an ointment or paste are more suitable, *e.g.* R Ichthyol gr. v, Liq. Picis Carbonis gr. xxx to dm. i, Past. Zinci Comp. B.P.C. ad oz. i. In the psoriasiform type more active preparations are necessary, such as oil of cade, the crude coal-tar paste recommended for chronic patches of eczema, and even chrysarobin. The X-rays are of great value, but the dosage must be carefully controlled.

In all cases of seborrhœic dermatitis it is essential to treat the scalp, which is so often the original source of infection. In men it should be shampooed with a tar soap twice or thrice a week, and on the nights before shampooing the following pomade should be well rubbed in: R Sulphur præcip. gr. xv to xxx, Acidi Salicylici gr. x to xx, Vaseline alb. dm. ii, Ol. cocois nuciferæ ad oz. i, Perfume q.s. Every morning the following lotion may be used: R Resorcin gr. x (to be omitted in persons with fair or grey hair), Acidi Salicylici gr. x, Hydrarg. perchloridi gr. $\frac{1}{4}$, Ol. Lavandulæ m. ii, Ol. ricini m. x, Spt. vini meth. indust. ad oz. i. In women the hair should be shampooed once or twice a week, and the pomade rubbed in the previous evening; the above lotion should be used daily, the castor oil being omitted from the prescription; but care should be taken to avoid irritation of the face and neck by the sulphur in the pomade, and a bathing-cap should be worn during the nights on which it is applied.

In cases of very acute seborrhœic dermatitis, or when eczematisation has occurred, soothing applications should be used, such as calamine liniment or an ichthyol cream, *e.g.* R Ichthyol gr. v, Ol. Olivæ, Zinci Oxidi āā oz. ss. Adip. lanæ anhyd. dm. i, Aq. Calcis dm. iii, and olive oil should be employed to clean the affected parts morning and evening.

TUBERCULOSIS

Active cutaneous tuberculosis of the skin may be classified as follows:—(1) Tuberculous chancre; (2) Tuberculous ulcer; (3) Tuberculous gumma; (4) Lupus verrucosus; (5) Lupus vulgaris. The two last and the tuberculides and sarcoids will be described.

LUPUS VULGARIS

This, the most familiar form of tuberculosis of the skin, is happily becoming much less common, and it is comparatively rare now to see the terrible mutilations that the disease is capable of producing. The primary lesion of lupus is a characteristic miliary nodule, embedded in the skin, and representing histologically

a minute infective granuloma ; it may conveniently be called a *lupoma*. In size it ranges from that of a pin's head to that of a large pea ; in colour it varies from yellowish- to brownish-red, with sometimes a bluish tinge ; it may form a raised papule or nodule on the surface of the skin, or may not project at all ; it has a translucent look and is soft in consistency, being easily pierced by a sharpened match. A patch of lupus may begin by the appearance of a single nodule of this kind, which gradually enlarges, while near it others are formed, or by two, three or more arising simultaneously. The patch spreads by the enlargement of individual nodules and the formation of new ones, and there is a tendency for these isolated lesions gradually to coalesce. Under vitropressure lupus nodules present a very characteristic appearance. They look, as Hutchinson aptly said, like specks of apple-jelly embedded in the skin, and their translucency is due to the local disappearance of the elastic and connective-tissue network.

If left untreated a patch of lupus tends to undergo one of two changes. In some cases spontaneous cicatrization takes place in the centre, while the patch tends slowly to extend at the borders by the formation of fresh nodules. But in the central, soft, white scar a few nodules persist or reappear, and this characteristic feature is of importance in the differential diagnosis between lupus and the serpiginous syphilides. In other cases the overlying epidermis is destroyed, so that there is ulceration with secondary pyogenic infection and the formation of impetiginous crusts.

There is very considerable variety in the clinical appearances of the disease according to the predominance of one or other of the above processes. Thus in some cases the nodules are small and superficial, and the patch is red, scaly, and projects hardly or not at all above the level of the surrounding skin. This type (*L. erythematoides*) is often mistaken for lupus erythematosus ; on vitropressure the characteristic apple-jelly nodules may be seen, but sometimes are only recognisable on microscopical examination. In other cases the nodules are large, confluent and raised to form a tumour (*L. tumidus* or *hypertrophicus*). Sometimes, probably as the result of secondary pyogenic infection, an ulcerating patch develops papillomatous vegetations, soft at first and later becoming warty, thus resembling lupus verrucosus (*q.v.*) (*L. papillomatosus*). Patches which ulcerate at the margin, while undergoing spontaneous cicatrization in the centre, imitate ulcerating syphilides (*L. serpiginosus*). Formerly the non-ulcerating forms of lupus were termed *L. non-exedens*, the ulcerating *L. exedens*, but this distinction is somewhat artificial. The most malignant type of ulcerating lupus—*L. vorax seu phagedænicus*—is fortunately rare ; it may rapidly produce the most frightful destruction and deformity.

The course of lupus is essentially chronic and its spread insidious. Although spontaneous involution with scarring commonly occurs, the disease extends peripherally, fresh nodules arise in the scarred area, and, except in *lupus disseminatus*, it is exceedingly rare for a natural cure to result.

Distribution. Lupus affects both the skin and mucous membranes. It may spread from the skin to the mucous membranes, but, as Audry insists, it is probable that the reverse is true far more commonly than was originally supposed. On the skin, the face is the commonest site (78 per cent. according to Sequeira). Emlyn Jones found that the disease started about the nose in 28 per cent., and in other parts of the face, including the auricles, in 48.4 per cent. In 1.8 per cent. the lips, in over 13 per cent. the neck, and in 8.5 per cent. the trunk or extremities were the primary sites. It is rarely seen on the scalp, forehead, upper eyelids, genitals, axillæ, or on the palms and soles.

The *mucous membranes* are affected in a large percentage of cases (43.25 per cent. among Sequeira's cases, 80 per cent. in Christiansen's series at the Finsen Institute). The nose, mouth, palate, pharynx, larynx, tongue, nasal duct, lachrymal sac, conjunctiva, and middle ear may be involved. The nose is by far the commonest site, and is frequently the primary source of involvement of

the skin. Sometimes the infection spreads up the nasal duct to the lower eyelid and conjunctiva, or from a primary tuberculous lesion of the conjunctiva it may spread downwards and invade the nasal mucous membrane, and thence the skin. On the palate, pharynx, and in the mouth lupus appears as a pinkish-red, mamillated patch, with here and there small ulcers, which may extend until the whole area is ulcerated and crusted. On the gums it produces swollen, red, fleshy granulations, and the teeth often become loose. On the tongue, a rare site, a papillomatous patch is the rule, but ulceration may occur.

Ætiology. The disease is due to the actual growth in the skin or mucous membrane of the tubercle bacillus, which may be either of a human or bovine strain, the proportion varying in different countries. From the researches of Griffith and others it is evident that in most cases the strain, whether human or bovine, is of low virulence. Although lupus may begin at any age, in more than half the cases it appears before the tenth, and in over 80 per cent. before the twentieth year. It is more than twice as common in females than males, and occurs far more in Northern Europe than in the South, partly, no doubt, because of the lack of sunlight, and is comparatively rare in the Colonies, the tropics, and in America. It affects, as a rule, scrofulous persons, who have been infected with tubercle in early life, and a strong family history of tuberculosis is often obtainable. It is almost invariably associated with tubercular adenitis, and sometimes with tuberculosis of bones, joints, or the peritoneum. As Besnier pointed out, phthisical persons do not develop lupus, whereas patients with lupus frequently become phthisical.

As regards the actual mode of infection of the skin, this may occur (1) directly from without; (2) by extension from deeper tubercular foci or from mucous membranes; (3) through the blood-stream. The first method is probably common, and doubtless accounts for the frequency of the disease in or around the nose, the organism being carried by dust or by the fingers; cases in which it has started in vaccination or tattoo marks, or after piercing the ears for ear-rings, have been recorded.

The second method is instanced by the occurrence of lupus in the skin over tuberculous glands, which have broken down or been excised, and by the spread of infection from the nasal mucous membrane, or *viâ* the nasal duct from the conjunctiva. The third method accounts for the multiple disseminated patches of lupus that appear most commonly after measles or whooping-cough, and it is probable that infection of the skin through the blood-stream is commoner than is usually believed.

Morbid Anatomy. The epidermis is usually atrophied, and beneath lies a mass of tubercular tissue, consisting of lymphocytes, epithelioid and plasma-cells, and here and there typical giant cell systems. There is destruction of the elastic and connective tissue, and of the blood vessels, and the newly-formed tissue undergoes degeneration without actual caseation. The histological picture, of course, varies according to the type of the disease, and the presence or absence of ulceration and secondary infection. Tubercle bacilli may be demonstrated, but, as a rule, only after prolonged search through serial sections.

Diagnosis. The conditions for which lupus is likely to be mistaken are tertiary syphilis, rodent ulcer, nodular leprosy, lupoid sycosis, certain forms of sarcoid, and lupus erythematosus; it is not uncommonly from carelessness confused with impetigo, impetiginised eczema and psoriasis.

From a tertiary syphilide it may be distinguished by the age of onset, by the length of history (since, with the exception of lupus vorax, lupus takes many years to produce lesions of the same extent as a syphilide of a few weeks or months standing), by the soft consistency of its nodules and their apple-jelly appearance on vitropressure, and by the presence of nodules in the central scar. Necrosis of bone is never caused by lupus. The Wassermann reaction should always be done, even if the diagnosis of lupus is certain, since there appear to be mixed cases—

usually lupus in a patient with congenital syphilis—in which antisypilitic treatment leads to striking improvement.

From lupus erythematosus the diagnosis may be difficult in certain cases. The chief points of distinction are the symmetrical distribution of lupus erythematosus (although by gradual spread lupus vulgaris may produce a bilaterally symmetrical patch over the nose and cheeks); the involvement of the scalp, edges of the ears, and fingers; the absence of ulceration and non-involvement of cartilage; and the different appearances on vitropressure.

A small nodular sarcoid may imitate lupus very closely, but the nodules in order, the histology is characteristic, and guinea-pig inoculations are always preservative.

like the age of onset, the hard, pearly, nodular edge, and the clean-cut ulceration the guinea rodent ulcer from lupus.

Complications. Apart from the disfigurement and mutilation that the disease may cause, the chief complications that occur are erysipelas and squamous-tended carcinoma. An attack of erysipelas may have a beneficial and even curative effect, as in the cases described by Hallopeau and Sequeira. Although carcinoma is a rare complication of lupus, particularly in women, its incidence has greatly increased since the introduction of the X-rays, the long-continued application of which is entirely unjustifiable in this disease.

Treatment. It must be remembered that the vast majority of patients with lupus have other tuberculous foci apart from the skin, and that a considerable proportion die from visceral tuberculosis. For this reason general treatment directed towards raising the patient's resistance in every possible way should be instituted. Heliotherapy, as carried out by Rollier at Leysin, is the method of choice, and is undoubtedly superior to any other known therapeutic measure. In England and countries which obtain relatively little sunshine, excellent results are achieved with the carbon-arc and mercury-vapour lamps. The introduction of this treatment has revolutionised the therapy of lupus and other forms of chronic tuberculosis, and has rendered unnecessary many of the local measures that were formerly employed. In addition, the internal administration of iodine and cod-liver oil is of great value. The former should be given in the form of a 10 per cent. solution in rectified spirit, of which 5 drops in milk may be taken at first twice daily, the dose being gradually increased up to as much as 60 drops *per diem* if well tolerated. Injections of tuberculin, if given prudently over a long period, are undoubtedly beneficial. Remarkable improvement is also sometimes obtained with intramuscular injections of calomel, but the results are inconstant.

Diet. In recent years, the dietetic treatment of lupus vulgaris and other tuberculous conditions of the skin, as advocated by Gerson and modified by Sauerbruch and Hermannsdorfer, has found increasing favour. The essentials of the dietary are: (1) the almost complete exclusion of sodium chloride, a compound rich in calcium but poor in sodium being used as a substitute (*e.g.*, Salarom); (2) liberal quantities of uncooked fresh vegetables, as salads with added fruit-juices, and extracts prepared by pressing uncooked vegetables; (3) the cooking of vegetables in their own juices with little water; (4) moderate restriction of meats; (5) restricted water-intake, but liberal amounts of the juices of fresh fruits and vegetables; (6) the administration of mineral compounds containing the lactate and phosphate of calcium, double salts of calcium and magnesium, strontium, aluminium, and silica, and cod-liver oil, thrice daily; (7) a high fat- and protein-intake, but a marked restriction of carbohydrates.

Local Treatment. Before employing any local measures for the destruction of the lupus tissue, it is advisable, in view of the remarkable results now being obtained by heliotherapy or the artificial light baths, to observe to what extent spontaneous healing will take place under such treatment, combined with the internal administration of iodine and cod-liver oil. From the cosmetic point of

view local phototherapy with the Finsen arc lamp undoubtedly gives the best results, the resulting scars being smooth and supple. The method is, however, very tedious and expensive. The modification of the Finsen Lamp, designed by Svend Lomholt, is a great improvement on the original one, and 80 per cent. of permanent cures have been obtained with it. The number of applications required is far fewer, the cosmetic results are excellent, and it can be used on the mucous membranes. The use of the X-rays should, as is now generally admitted, be reserved for the ulcerating, vegetating or papillomatous types of the disease. It may be combined with the application of the galvano-cautery, or with periodical scarification. Large doses of X-rays, or their continued use over long periods, are entirely unjustifiable owing to the risk of a subsequent radiodermatitis, with ultimate epitheliomatous degeneration of the scar. The thermocautery and galvano-cautery are useful adjuncts to treatment, and are of particular value in lupus of the mucous membranes. Recently, diathermy has been employed with excellent effect. Scarification, if correctly performed, gives scars hardly less satisfactory than those obtained with the Finsen lamp, but it is a tedious and painful method; it is, however, the method of choice for rapidly extending, vegetating lupus (*L. vorax*), and for the treatment of nodules embedded in scars. In France the filiforme douche is being used with good results for the destruction of lupus tissue. Various caustics, such as arsenious acid, pyrogallol acid, trichloroacetic acid, the liquid acid nitrate of mercury, and a combination of salicylic acid and creosote in plaster form have a selective action on lupus tissue, but cause considerable pain, particularly arsenious acid. Adamson's method of employing the liquid acid nitrate of mercury is simple and gives excellent results. It is carried out as follows:—The lupus nodules are gently rubbed for from one to two minutes with a piece of cotton wool, twisted round the closed ends of a finely pointed pair of forceps, and moistened with the liquid. No subsequent dressing is necessary, although it is perhaps advisable to keep the treated surface covered with a piece of clean lint or gauze. A good deal of inflammatory reaction ensues, and a scab forms, which becomes detached in course of time, leaving a smooth pink surface. The subsequent scar compares favourably with that obtained by any other method, except, perhaps, the Finsen light. The method is rather painful, but an anæsthetic is not usually required. A considerable area can be treated at one sitting, and the applications can be repeated until all the active lupus tissue has been destroyed. In cases in which the nodules are large and deep, they may first be scraped under anæsthesia, and then treated with the acid nitrate of mercury or zinc chloride.

LUPUS VERRUCOSUS

(*Verruca necrogenica*)

This variety of tuberculosis of the skin is caused by direct inoculation of tubercle bacilli. It may arise in phthisical or other patients suffering from "open" tuberculosis as a result of auto-inoculation. More commonly it is met with in medical men, nurses, or students in contact with tuberculous patients, or in pathologists, *post-mortem* attendants, veterinary surgeons, butchers, and others who handle human or animal cadavers infected with tubercle. The lesions contain considerable numbers of tubercle bacilli, far more than those of lupus vulgaris, but less than tuberculous ulcers. They are met with usually on the hands, particularly on the thumb, but they also occur on the elbows, knees, feet, buttocks, peri-anal region, neck, and even on the face. The earliest lesion is a small erythematous nodule, from which, later, a bead of pus can be expressed; it gradually enlarges to form a warty plaque, surrounded by a bluish halo of erythema. In a fully-developed patch three zones can be recognised: at the periphery an erythematous area, within this a number of papillomatous nodules of a bluish-violet colour covered with adherent crusts, and in the centre

either a depressed scar or brownish warty projections, separated by fissures. A small quantity of pus, in which tubercle bacilli may be found, exudes from the surface, and the base of the plaque is indurated. The lymphatic glands are infected early, and the viscera may become involved.

Treatment. The method of choice is excision of the affected area of skin as soon as the diagnosis is established, or total destruction of the lesion with the actual cautery or by diathermy. Sequeira recommends removal of the warty surface with pyrogallic or salicylic acid, followed by the application of X-rays.

THE TUBERCULIDES

In 1896, Darier introduced the term "tuberculides" to designate a group of eruptions which occur in persons having a manifest tuberculous infection, and which, although differing from each other in their clinical appearances, are frequently co-existent in the same patient, thus indicating their relationship and common origin.

Classification. A. CUTANEOUS TUBERCULIDES, in which the lesions are dermo-epidermic.

- (1) *Lichenoid Tuberculide*. Lichen scrofulosorum.
- (2) *Eczematoid Tuberculide*. Dermatitis scrofulosa—a variety of the above.
- (3) *Papulo-necrotic Tuberculides*. Folliclis. Acnitis.
- (4) *Acneiform Tuberculide*. Acne cachecticorum—a variety of the papulo-necrotic type.
- (5) *Lupoid Tuberculide*. Papular sarcoid of Boeck, or disseminated miliary lupoid, with which acnitis may be associated.
- (6) *Erythemato-atrophic Tuberculides*. Lupus erythematosus in certain cases.
- (7) *Rosaceous Tuberculide*.

B. SUBCUTANEOUS TUBERCULIDES.

Erythema induratum scrofulosorum (Bazin's Disease).

Erythema nodosum (in some cases).

Subcutaneous sarcoid of Darier-Roussy.

Ætiology of the Tuberculides. The tuberculides result from the embolism in a blood vessel either of the skin or subcutaneous tissue of tubercle bacilli, carried in the blood-stream from some local tuberculous lesion. They occur in persons who have been usually, if not always, sensitised to tubercle by an infection in early life, and whose resistance to the infection is, as a rule, good. The actual lesions represent inflammatory reactions produced by the interaction of the antibodies present in the sensitised tissues and the bacilli, this reaction bringing about destruction of the latter, so that the lesions heal with or without scar formation. It is obvious that for their occurrence the presence of antibodies is essential, and this probably explains why disseminated patches of true lupus may follow an attack of measles in a tuberculous person, since measles causes a temporary disappearance of tuberculous antibodies, so that the bacilli survive and multiply. An important factor in the genesis of tuberculides is circulatory stasis; the papulo-necrotic variety is seen in scrofulous persons with a chilblain-circulation, the sites of election being those in which the blood flow is most stagnant, and erythema induratum occurs almost exclusively in young females with cyanotic, cedematous-looking legs. As might be expected, owing to the rapid destruction of the bacilli, it is only rarely that they are demonstrable in tuberculide lesions. They have, however, been found in lichen scrofulosorum and erythema induratum. Inoculation of guinea-pigs with tissue from the lesions has more often given positive results. Injections of tuberculin not only give rise

to focal cutaneous reactions, but may provoke an outbreak in a tuberculous person of tuberculides not previously present. Moreover, minute doses of tuberculin, given at suitable intervals, have a striking curative effect in erythema induratum and the papulo-necrotic tuberculides.

Treatment of the Tuberculides. The general treatment of patients with tuberculides is the same as that already outlined for lupus vulgaris (*q.v.*). Injections of small doses of tuberculin intradermically, in combination with intravenous injections of novarsenobillon, are strongly recommended by Darier. The writer has obtained good results in folliclis and erythema induratum with injections of gold compounds, such as are employed in lupus erythematosus (*q.v.*), iodine and cod-liver oil internally, and total ultra-violet light baths. In erythema induratum, complete rest in bed, particularly in cases with ulceration, should be enjoined until the lesions have healed.

Lichen Scrofulosorum. This, the lichenoid type of tuberculide, is comparable to the lichenoid trichophytide, and to the papulo-follicular eruption, first described by Whitfield, in association with severe streptococcal impetigo (lichenoid streptococcide).

The eruption consists of two types of lesion—plane papules resembling somewhat those of lichen planus, and follicular papules, which vary considerably in appearance. The former are small, flat, polygonal, and yellowish or reddish in colour. They may be smooth and glistening, or covered by a small scale. The follicular papules may exist alone, but are more commonly seen in association with the plane variety. They are formed around the pilosebaceous follicles, are conical or acuminate in form, reddish in colour, and occasionally capped by a horny spine (one form of lichen spinulosus, *cp.* the lichenoid trichophytide). Sometimes vesico-pustules may form at their summits (*cp.* vesiculo-pustular trichophytides).

The various types of lesion are arranged in roundish groups, or circles, or segments of circles. They are distributed chiefly on the trunk, particularly on the flanks, more rarely on the limbs, and occasionally on the face. Itching is slight or absent. The eruption progresses by the appearance of fresh crops of papules from time to time, so that it may last for months.

Morbid Anatomy. The lesions are formed by a tuberculoid infiltration of the dermis with epithelioid and giant cells: there is little or no tendency to caseous degeneration. The infiltration is situated either in the papillary layer, or around a pilosebaceous follicle, according to the type of papule examined.

Ætiology. The eruption is, with the eczematoid variety, the simplest and most superficial of the tuberculides. It would appear to represent, with phlyctenular ophthalmic lesions, the first manifestation of tuberculous bacillæmia after the barrier afforded by the lymphatic glands is broken; hence its usual incidence in childhood. Boeck and Bruusgaard have described it as occurring in a child of sixteen months six weeks after the healing of a digital tuberculous chancre, and immediately after a phlyctenular keratitis; in another case, a girl of one year, with a vulvar tuberculous chancre and inguinal adenitis, keratitis developed before the healing of the chancre, and three months later an eruption of lichen scrofulosorum.

Tubercle bacilli have actually been demonstrated in microscopical sections of the papules, and positive inoculations have been obtained in a guinea-pig. Local, focal, and general reactions result from injection of tuberculin, and the eruption may be provoked by such injections in tuberculous persons. Adamson and Brocq have observed the development of follicular papules around the site of an intradermal injection of tuberculin. Cases have been recorded in which lichen scrofulosorum cleared up spontaneously after surgical removal of tuberculous glands.

Eczematoid Tuberculide. Boeck many years ago described, as attenuated forms of lichen scrofulosorum, a “disseminated papulo-squamous tuberculide”

and an "eczema scrofulosorum." Jadassohn has also indicated a scaly form of the eruption, in which somewhat infiltrated patches, reddish-brown in colour, and resembling those of psoriasis or seborrhœic dermatitis, are seen. Schaumann and others have seen such patches associated with typical lichen scrofulosorum, and on section the former found a tuberculoid structure with giant-cells, but without necrosis.

There has been described (21) a series of cases of an eczematoid dermatitis, occurring almost exclusively in children and adolescents, as scaly patches of a characteristic fawn or pale brown colour, usually dry, but sometimes oozing—probably as a result of scratching or rubbing—and situated chiefly on the extensor surfaces of the limbs, the trunk, and on the face, particularly on the temples and forehead below the margin of the hair. In about 80 per cent. of the cases definite signs of active tuberculosis were demonstrated. The writer named the eruption dermatitis scrofulosa. Later a further series of these cases was described (22) and it was shown (1) that exactly similar patches may arise *de novo*, and persist for some time in tuberculous children at the sites where Pirquet's cuti-test with tuberculin has been done, and (2) that in children with dermatitis scrofulosa patches, identical in appearance and histological structure with those already present, may be produced by applying tuberculin to the skin. Cases of undoubted lichen scrofulosorum were also observed, in which patches of dermatitis scrofulosa were co-existent, and the view was put forward that the latter is an eczematoid variety of the former.

The probable explanation of this eczematoid form of tuberculide is that it results from *epidermal* sensitisation to tuberculin, since every eczematous reaction is dependent upon sensitisation of the cells of the rete Malpighii. The experimental production of patches of dermatitis scrofulosa by the application of tuberculin to the skin, above referred to, is in favour of this view.

Diagnosis. The eruptions with which dermatitis scrofulosa is most likely to be confused are the dry scaly form of streptococcal impetigo, the scaly patches that result from the use of strongly alkaline soaps, and those due to infection with the pityrosporon. None of these have the same fawn or reddish-brown colour, nor is there in them the same degree of infiltration that characterises dermatitis scrofulosa.

Papulo-Necrotic Tuberculide. This form of tuberculide is not uncommon, and is seen chiefly in adolescents and young adults with a poor peripheral circulation and tuberculosis of the glands, bones, joints, or peritoneum. The elementary lesion is a small firm papule, surrounded by a reddish border, and embedded in the dermis. The central portion becomes bluish in colour, and there forms beneath its epidermis a vesiculo-pustule, which, on being opened, exudes a sero-purulent fluid and exposes a small necrotic cavity. When untouched, the pustule dries up to form a crust, which covers the central necrotic area; when this falls, a pitted scar is left, surrounded by a narrow zone of pigmentation.

The distribution of the lesions to a great extent corresponds to the sites of maximum vascular stasis, and they are found principally on the hands and feet, the elbows and knees, the extensor surfaces of the forearms, the ears, and the rosaceous area of the face. They appear in crops, particularly in winter, when the peripheral circulation is most sluggish, and may continue to do so for months or years. As with erythema induratum, however, the eruption tends to disappear spontaneously, even without treatment, as the patient approaches middle age.

Morbid Anatomy. The lesions presumably result from embolism of tubercle bacilli in a small dermic vessel, as a result of which an area of necrosis is formed in the connective tissue; this becomes surrounded by a zone of inflammation, which may have a definitely tubercular structure, epithelioid and giant-cells being found in irregular groups. The site of necrosis varies, being very superficial in so-called acne cachecticorum.

Ætiology. Like lichen scrofulosorum, the papulo-necrotic tuberculides may be the first manifestation of bacillæmia. Bruusgaard observed a case, a boy of seventeen months, in which they appeared shortly after the healing of a tuberculous chancre of the chin. From the tuberculides a guinea-pig was successfully inoculated, and a bacillus of the human type was cultivated.

Lupus Miliaris Faciei (Papular Sarcoid of Boeck). This eruption, which Schaumann rightly distinguishes from the true sarcoids that form part of his benign granuloma, is best classified among the tuberculides; in some respects it appears to provide a transition between these and the active tuberculous dermatoses, such as lupus vulgaris. Schaumann considers that it should include the follicular disseminated lupus of Tilbury Fox, the acne agminata of Crocker, and the acnitis of Barthélemy.

It consists of hemispherical papules, of the size of a millet-seed to that of a pea, reddish-blue or brownish in colour, and moderately firm to the touch. They are arranged symmetrically on the face, particularly over the rosaceous area, on the neck, and less commonly on the wrists, extensor surfaces of the upper limbs, shoulders and back, scalp and lower limbs. They may appear quite suddenly, and continue to form crops over a long period of time: they may be absorbed, leaving scarcely perceptible cicatrices, or undergo visible necrosis, with superficial suppuration, and subsequent pitted scarring (acnitis). Some would separate the latter form from the non-ulcerative type of eruption, but the two may, as Schaumann points out, coexist, and histologically one may find evidence of necrosis both in the lupoid papules, and in those with suppuration.

Morbid Anatomy. Histologically the papules are found to consist of masses of epithelioid cells, with or without giant cells, mingled with numerous lymphocytes. Central caseation is often seen.

Ætiology. The eruption may appear in advanced cases of phthisis, but more commonly the clinical evidence of tuberculosis in those affected is not striking, particularly in the purely lupoid form, which is seen chiefly in women of middle age. Radiographic examination of the chest usually reveals evidence of old hilus phthisis, with calcification of the bronchial glands, and sometimes of a former apical lesion, but, according to Schaumann, the lungs never show the shadows seen in benign lymphogranuloma. Tubercle bacilli have been found in the lesions by several observers, and others have obtained positive animal inoculations. The intradermal tuberculin test is always positive, according to Schaumann.

Rosaceous Tuberculide. This variety of tuberculide differs from the above in that the rosaceous element (flushing, telangiectasia, and scaliness) is more apparent, the lesions are smaller and more superficial, and there is less tendency to scarring. Histologically, although their structure is tuberculoid, the classic tubercle with central caseation is not found.

The condition was first described by Lewandowsky, and many cases have since been reported (23). The lesions consist of minute papules, sometimes but not always follicular, and irregularly distributed; although usually discrete, they may be grouped in small patches. Their colour varies from bright red to brownish yellow. On vitropressure they resemble lupoid nodules, unlike the papules of true rosacea. Some of them may become pustular, but the pustules are small and superficial. The degree of rosaceous flushing and of telangiectasia varies.

The lesions persist for a considerable time and then slowly undergo involution, either leaving no visible trace or a small pitted scar. The diagnosis from papulopustular rosacea is sometimes difficult, the main points being the lupoid appearance of the papules both with and without vitropressure; the involvement of the lateral parts of the forehead and cheeks and of the neck; oily seborrhœa, usually present in rosacea, is as a rule absent or slight, and the tendency to pustulation is much less, the pustules, when present, being small and superficial; the

histological structure of the lesions ; the sensitiveness of the skin to tuberculin (intradermal and Moro tests), but in some cases this is slight.

Morbid Anatomy. In chronic indurated papules of ordinary rosacea a tuberculoid structure with occasional giant-cells is sometimes found as a reaction to broken-down follicles and sebaceous glands. In rosaceous tuberculide even minute and recent papules reveal circumscribed tuberculoid infiltrates, lying just below the epidermis, with giant-cells here and there. They may be perifollicular or around a sweat-duct, but are often independent of the glandular appendages, unlike those of rosacea.

Treatment. Apart from the general treatment already indicated for tuberculous conditions of the skin, injections of gold compounds have been found by the writer and others to be of great value.

Erythema Induratum (Bazin's Disease). Under the term erythema induratum two types of indolent subcutaneous nodules are included, the one tuberculous the other not. The former is commonly known in this country as Bazin's Disease, and is seen almost exclusively in young girls with fat, cyanotic, œdematous legs, in which there is vascular stasis, most evident on the postero-external surface of the lowest third ("erythrocyanosis crurum puellaris"). Since the nodules are of embolic origin, they occur most commonly on this area. They appear as deeply indurated, reddish or violet plaques of varying size, which may slowly resolve, or rupture, exuding an oily fluid, the product of fat-necrosis ; in the latter case indolent ulcers result, which become secondarily infected with pyogenic organisms. As might be expected, the occurrence of fresh nodules is predisposed to by long periods of standing, which increase the vascular stasis, and their resolution is hastened by rest in bed.

Morbid Anatomy. It is probable, as Schaumann suggests, that in erythema induratum, and the subcutaneous variety of sarcoid, the tubercle bacilli come to rest in one of the vasa vasorum of a subcutaneous vein, with the result that there occurs a thrombo-phlebitis. Around the embolised vessel there may be a tuberculoid infiltration in the wall of the vein. As in erythema nodosum there is extensive necrosis of the subcutaneous fat, the products of which are absorbed by histiocytes and giant-cells.

Ætiology. This variety of erythema induratum is probably always of tuberculous origin. Numerous successful animal inoculations with material from the nodules have been made. Strongly positive cutaneous and intradermal tests are obtained with tuberculin, and marked focal reactions occur if it be injected. Like lichen scrofulosorum, the eruption may arise for the first time in a tuberculous person after a therapeutic injection of tuberculin. Not uncommonly papulo-necrotic tuberculides and erythema induratum coexist in the same patient.

Subcutaneous Sarcoid of Darier-Roussy. This variety of tuberculide is very closely allied to the tuberculous form of erythema induratum. The lesions consist of indolent hypodermic nodules, varying in size from that of a pea to that of a walnut, or may be even larger. They may become more or less confluent and form nodular plaques. The overlying skin is of normal colour or bluish, and in places adherent. They occur in adults of both sexes, rarely in children. The sites of election are the scapular region, the sides of the chest, the flanks, and the thighs ; but they may also be met with on the arms and legs, and even the scalp. Unlike erythema induratum and tuberculous gummata, they never undergo necrosis with ulceration.

Morbid Anatomy. The histological appearances resemble those of erythema induratum, but the tuberculous structure is more apparent. Typical giant-cell systems are found, in combination with fat necrosis.

Ætiology. Successful animal inoculations have been made with the tissue from the nodules, and positive local and focal reactions obtained with tuberculin.

SARCOIDS

A very important group of eruptions may be conveniently classified under the term *sarcoid*, but considerable confusion still exists concerning them. In the following account the views of Schaumann (24), to whom we owe the conception of a *benign lymphogranuloma*, will be largely adhered to, although further research may demand their modification.

The types of eruption to which the term sarcoid has been applied are as follows :

- (1) *Multiple benign papular sarcoid of Boeck*, by many now called disseminated miliary lupoid.
- (2) The large nodular benign sarcoid of Boeck.
- (3) The hypodermic sarcoid of Darier-Roussy.
- (4) Lupus pernio.

According to Schaumann, the small papular and the hypodermic varieties should be classed among the tuberculides (*q.v.*), whereas the large nodular cutaneous sarcoid and lupus pernio should be regarded as part of his benign lymphogranuloma, and grouped with the tubercular form of lupus erythematosus, and the malignant lymphogranuloma of Sternberg (Hodgkin's disease) as paratuberculosis.

Lupus Pernio and Nodular Benign Sarcoid (*Benign Lymphogranuloma*). Thanks to Schaumann's researches, it is now recognised that these are the cutaneous lesions of a widespread and chronic form of granuloma, which involves, apart from the skin and subcutaneous tissue, the lymphatic glands, the tonsils, the bones of the extremities, the lungs, the spleen and the liver. Severe cases of the disease are rare. In them may be seen lupus pernio of the face, ears, and extremities, combined with multiple sarcoid lesions, varying from superficial lupoid nodules to large subcutaneous tumours, and radiograms of the bones of the hands and feet and of the lungs may reveal extensive involvement. On the other hand, milder cases, with a few scattered sarcoid nodules of moderate size and without lupus pernio or evidence of affection of the bones and lungs, are not uncommon.

Lupus Pernio. This term is given to a diffuse symmetrical infiltration involving the nose, malar regions, pinnae, the backs of the hands, the fingers, and more rarely the toes. The consistency of the swellings is doughy, the colour bluish-grey, sometimes with a reddish tinge. The fingers become fusiform in shape, and there may be deformity from destruction of the underlying bones (*spina ventosa*). Sometimes there is ulceration, with subsequent scarring.

Nodular Sarcoid. The most superficial nodules are yellowish-red in colour, grouped, and resemble very closely those of lupus vulgaris, but are harder. Others vary in size from that of a pea to that of a walnut, may be rose-coloured or greyish, and often have a characteristic translucent appearance. The largest lesions form dermic or hypodermic swellings, sometimes as large as a hen's egg, bluish-grey in colour, like lupus pernio, and situated chiefly on the arms, legs, trunk, and malar regions of the face. Resolution may occur, leaving the overlying skin flaccid, or there may be ulceration and crusting of the surface.

There is also a rare variety of sarcoid which merits separate description. It is seen most commonly in women, and the lesions are found principally on the scalp, forehead, temples, ears and neck. The elementary lesion is a raised nodule, resembling in colour and appearance very closely that of lupus vulgaris; the nodules tend to arise in groups, and to spread peripherally, while undergoing resolution with scarring in the centre. In this way complete or incomplete rings are formed enclosing a depressed cicatricial centre. The borders are constituted by the reddish-yellow sarcoid infiltration. The condition is apt to be mistaken for the multiple superficial form of basal-celled carcinoma, but the "apple-jelly" colour of the edges should prevent confusion. Numbers of these lesions,

varying in their stage of evolution from single circular or oval nodules to discrete or confluent rings of considerable extent, may be found in the above situations. They leave permanent scars, which, of course, give rise to cicatricial areas of alopecia on the scalp.

Morbid Anatomy. Lupus pernio and the sarcoid nodules consist of lobular masses of epithelioid cells, lymphocytes, and occasional giant-cells, separated by strands of connective tissue. As has been said, nodules, having the same histological structure, occur in the lymphatic glands, tonsils, the medulla of the bones of the extremities, and lungs. In the bones they lead to destruction of the osseous tissue, and give rise to characteristic areas of absorption, which appear dark in radiographic plates. These areas are mostly circular and sharply defined, but they may be irregular if the destructive process is extensive. They are seen chiefly in the phalanges, and in the metacarpals and metatarsals near their extremities, but may also occur in the bones of the carpus and tarsus, and even at the ends of the long bones. As the deposits occur primarily in the bone-marrow, this may be extensively affected without there being necessarily any changes in the bony tissue.

Ætiology. In Schaumann's opinion the origin of his benign lymphogranuloma, of which lupus pernio and nodular sarcoid are the cutaneous manifestations, is an infection with the *filterable* form of the tubercle bacillus, probably of the bovine type. He inoculated into guinea-pigs the sputa of three patients, and only after passage through several animals was he able to produce the classical form of experimental tuberculosis and cultivate the bacillus, which in two of the cases was of the bovine type, in the other of atypical form. He also claims in favour of a tuberculous causation the fact that in true benign lymphogranuloma the Von Pirquet reaction is invariably negative, the patients being, in fact, less sensitive to tuberculin than normal persons, and he believes it impossible for the tuberculides, which are associated with a high degree of cutaneous allergy and strongly positive tuberculin reactions, to coexist with benign lymphogranuloma.

In some of Schaumann's cases pulmonary tuberculosis developed, and this involvement of the lungs caused the cutaneous sarcoid lesions to disappear, and the Von Pirquet to become positive. It should be remarked, however, that tuberculides and even lupus vulgaris also usually disappear if actively progressive phthisis ensue, and, with the extension of the lung disease, the Von Pirquet reaction diminishes, and finally becomes negative.

Treatment. The writer has obtained satisfactory results in some cases with injections of gold compounds, as indicated for the treatment of lupus erythematosus. Gray has found intramuscular injections of sodium morrhuate of great value, and in one case under the writer's care—the most extensive and characteristic example of benign lymphogranuloma that he has seen—they were given, in combination with iodine and cod-liver oil internally and artificial sunlight baths, and the ultimate result was very striking.

Darier advises *intra-dermal* injections of tuberculin with novarsenobillon intravenously. Schaumann has failed to obtain results either with the latter or with arsenic by mouth. Hudelo, Montfaur and Leforestier have recorded success in a case of lupus pernio with injections of large doses of cacodylate of soda. Recently Lomholt has reported disappearance or improvement of the lesions with injections of antileprol.

SOFT SORE

(*Soft Chancre, Chancroid*)

A soft sore or chancre is a round or oval ulcer, which develops very rapidly after a short incubation period, and is auto-inoculable. At the site of invasion by the specific infecting organism (*Bacillus of Ducrey-Unna*) a small inflammatory

papule appears within twelve to twenty-four hours, which soon becomes converted into a pustule on a bright red base. On rupture of the pustule, the characteristic ulcer is formed—i.e., within four or five days from the date of inoculation. *The base* of this ulcer consists of greyish granulations, covered with a yellow, creamy, purulent film; *the edges* are sharply cut or undermined, and careful examination will show slight crenation—a valuable diagnostic sign; *the base* is œdematous, but not indurated like that of a chancre; *the periphery* of the lesion is bright red. The ulcer exudes a purulent secretion, from which inoculation of adjacent areas of skin takes place. It is, therefore, rare to see a single lesion, multiple ulcers, arising either from simultaneous inoculation at more than one point, or from auto-inoculation from an original single sore, being the rule. By the confluence of several lesions, the size of which varies from a pea to a finger-nail, a considerable area of ulceration may result.

The neighbouring *lymphatic glands*, on one, or more rarely, both sides, are, as a rule, enlarged and painful within a few days from the appearance of the sore or sores, and there is a tendency for one gland in particular to be involved, which is very apt to soften and break through the skin, producing the soft or chancroidal bubo.

The situation of soft sores varies, but the vast majority are seen on the genitals and adjacent parts. In men the prepuce, the corona and cervix, and the frenum, which may be perforated, are most commonly affected; in women, the vestibule, the fourchette, the labia minora, the glans clitoridis, and the anus. By auto-inoculation, neighbouring regions, such as the pubis, internatal cleft, and inner surfaces of the thighs, may be involved. Extra-genital soft sores are excessively rare, and usually, though not invariably, arise by auto-inoculation from genital lesions.

Complications. Reference has already been made to suppurating bubo; in addition lymphangitis, abscess of the dorsal lymphatics of the penis (bubonulus), phimosis, paraphimosis, phagedena, and gangrene may result. Phagedena arises both from the actual sores, and also from a suppurating bubo.

Ætiology. The cause of soft sore is a strepto-bacillus described by Ducrey and Unna. It is a short Gram-negative bacillus, easily stained by methylene-blue. It is with difficulty grown artificially, but has been cultured on peptonised human skin and certain other special media. The organism may be successfully inoculated on monkeys. Infection usually takes place directly by sexual intercourse, but may rarely be indirect.

Diagnosis. The chief characteristics of soft sore are the short incubation period, the tendency to rapid ulceration, the auto-inoculability and the resulting multiplicity of the lesions, the early involvement of the lymphatic glands and their liability to suppuration, the lack of induration of the base, the crenated edge of the ulcer, and the painful course of the affection. It must be distinguished from a syphilitic chancre, herpes progenitalis, the lesions of scabies, mucous patches, tertiary gummatous ulceration, and epithelioma.

The following differences between hard and soft chancres should be noted (Pusey):—

<i>Hard Chancres</i>	<i>Soft Chancres</i>
Incubation period two to five weeks.	Incubation period two or three days; becomes an ulcer in four or five days.
An erosion or superficial ulcer, with sloping edges and scant secretion.	An angry-looking ulcer with a bright-red halo, undermined edges, crenated border, and profuse purulent secretion.
Indurated cartilaginous base.	Slight inflammatory induration.
Is almost painless.	Often very painful.

Hard Chancres

Is not auto-inoculable.

If multiple, due to multiple primary inoculations, the lesions being of the same age.

Adenitis is bilateral.

Adenitis indolent and painless; the enlarged glands are multiple and discrete.

Soft Chancres

Is auto-inoculable, and therefore multiple lesions of different ages and sizes are common.

Adenitis usually unilateral.

Adenitis acute, painful and inflammatory, and likely to result in suppurating bubo.

It must be remembered, however, that a simultaneous inoculation with Ducrey's bacillus and the *Treponema pallidum* may occur, and for this reason every soft sore should be considered as potentially a hard chancre. Frequent and persistent examinations for the spirochæta of serum taken from the edges of the ulcer, after a preliminary cleansing of the surface, should be made.

Treatment. The patient should, if possible, be kept at rest, since exercise favours suppurative adenitis. The ulcer should be cleaned several times daily with hot solutions of perchloride of mercury (1 in 2,000), potassium permanganate (1 in 1,000), or carbolic acid (1 or 2 per cent.), and iodoform or aristol powder then applied freely. Another method is to destroy the ulcer by swabbing it thoroughly with pure carbolic acid, applied with a swab of cotton-wool; an acute inflammatory reaction occurs, and a slough is formed and shed, leaving a healthy wound.

RHINOSCLEROMA

This is a dense infiltration of the septum and alæ of the nose, rendering it as hard as ivory, thick, and rigid. The surface is smooth or irregular, the colour normal or brownish red; the mucous membrane is affected as well, and the orifices may be blocked by its swelling. By extension the upper and lower lips, the gums, epiglottis, larynx, trachea, jaws, and soft palate, which may be perforated, may become involved. The changes are a dense infiltration of the corium and papillæ with plasma cells, the presence of large translucent degenerated cells (Mikulicz cells), and bacilli, the bacilli of Frisch, which have a close resemblance to the pneumonia bacilli of Friedländer, and are found chiefly in the Mikulicz cells, but also in the plasma cells and tissue. Removal by the knife or destruction by caustics may be required, but X-rays should be tried first.

The majority of cases have occurred in southern Russia, Egypt, Italy, and "on both shores of the Danube" (Castex). Several have been reported in America, only one of which was indigenous.

Erysipeloid. This eruption was first described by Morratt Baker as "erythema serpens," and later by Rosenbach, who gave to it the name under which it is now known. It is usually seen on the hands, but may occur on the face and elsewhere. Recent researches have shown that it is due to accidental infection of the skin with the bacillus of swine-erysipelas, which is saprophytic on animal matter. The eruption begins as an erythema surrounding the point of inoculation, usually a cut or scratch. It spreads peripherally, while clearing in the centre. The colour is bluish-red, and the border is raised and well-defined. By the development of new areas irregular circinate figures may result. Subjective symptoms are slight, as a rule, but itching and some pain may occur. The infection runs a definite course of some two to four weeks.

Apart, however, from this mild form of the disease, another more serious (25) is occasionally seen. The eruption may spread widely and involve at different times almost the entire skin. Lymphangitis and arthritis with general malaise and fever accompany it, and, although spontaneous recovery usually follows in some weeks, the course may be chronic. An acute, septicæmic variety, with

arthritis and endocarditis, has occurred in veterinary surgeons accidentally inoculated when immunising swine against the infection.

Ætiology. The disease occurs principally in those who handle meat, fish, crustacea, hides, and bones. Gilchrist recorded 323 cases in which a bite or injury from crabs was responsible, the incubation period being two days. It is rare in England, but in America is an occupational disease of importance, particularly in those engaged in the fish industry.

Treatment. The affected area should be painted with iodine or ichthyol. In severe cases injections of an immune serum have proved of value.

Diseases Due to Fungi (Mycoses)

The dermatomycoses are described elsewhere, *i.e.* Actinomycosis on p. 99, Blastomycosis on p. 102, and in the section dealing with Diseases of the Tropics, p. 1028.

EPIDERMATOMYCOSES

FAVUS

In this disease, rare in England, the fungus attacks the epidermis and the hair follicles; it may at first form patches like those of ordinary ringworm, but soon there appears a small, bright yellow, circular disc, with a depressed centre and a gradually thinning margin. This, the "favus cup," is caused by the fungus elements separating the layers of the epidermis and lifting them up, except at the central point, where the hair follicle joins the skin. This characteristic lesion may occur on the scalp, or on any other part of the body, the forearm for instance, determined by contagion; and it is conveyed not only from man to man, but to man from domestic animals—rabbits, dogs, cats, and others. When numerous cups have formed, they become aggregated together, and produce a thick continuous yellow crust, with an irregular honeycombed surface, giving off an offensive odour resembling that of mice. The hair sacs are destroyed, the hairs fall out, and baldness results; moreover, the favus masses often become a nidus for pediculi, and eczema and impetigo complicate the original lesion. If the masses are examined under the microscope, after soaking in liquor potassæ, the mycelium and spores (conidia) of the *Achorion schönleinii* are seen. The conidia are larger and more varied than those of the ringworm fungi, and the mycelium is shorter and more jointed.

The *nails* may be also invaded by the fungus of favus. They present an appearance similar to that in ringworm and sometimes a distinct cup forms under the nail. The nail may be examined in the same way as in ringworm.

Two other species of achorion have been seen in man in rare cases: *Achorion Quinckeanum*, the fungus of mouse favus, and *Achorion gypseum*.

Treatment. The crusts must be softened by oil or poultices and removed; parasitocides and epilation are needed, and for most cases the Röntgen rays should be used as for ringworm. The nails, if affected, may be treated in the same way as when they are diseased by the microsporon or trichophyton. The disease is very obstinate, and after apparent cure often breaks out again. It is well to care for the general health by good food and tonic medicines.

RINGWORM (*See Plate 59*)

Tinea or ringworm is the term used for an infection of the skin, hair, and nails with various species of fungi. All of them have segmented mycelia and form "spores," the size of which has been utilised rather unscientifically as a basis for classification. For clinical purposes, however, we recognise: *Microsporon*s or small-spored ringworms, which include the *M. audouinii*, responsible in the great majority of cases for ringworm of the scalp in this country and for

some of *tinea circinata*, and other species which infect animals and indirectly human beings, e.g. *M. felineum*, *equinum*, *canis vel lanosum* : *Trichophyttons* or large-spored ringworms. These are divided into *endothrix* varieties, in which the fungus is found only inside the fully infected hairs, and *ecto* or *ecto-endothrix* varieties in which it is seen both inside and outside the hair. The former apparently affect only man and birds ; the latter occur in many animals (horses, dogs, cats, cattle, deer, and birds), but may be communicated to man. *Epidermophyttons*, which do not invade the hair, but grow only in the horny layer of the skin and in the nails. The best known of these is the *E. inguinale*, which is peculiar to man, and is the cause of *tinea cruris* or "dhobi itch" and of the common intertriginous ringworm of the hands and feet.

These fungi can be cultured on artificial media, and it is their cultural characteristics that enable us to classify them scientifically.

Clinically ringworm is classified to some extent according to the site affected. Thus we speak of *Tinea tonsurans* (ringworm of the scalp), *T. circinata* (ringworm of the glabrous skin), *T. sycosis* (ringworm of the beard), *T. unguium* (ringworm of the nails), and *T. cruris* (ringworm of the crutch, also termed "eczema marginatum," "dhobi itch," and "Burmese ringworm").

***Tinea tonsurans* (Ringworm of the head).** This disease is the great scourge of schools and allied institutions among the poorer classes. It is frequent in children, rare in infancy, and not easily caught by adults. It spreads by contact, and by the use of hats, caps, brushes, combs, and towels used in common.

It generally first appears as a round patch on which the growth of hair seems thinner than elsewhere. On close examination the skin is seen to be pink, perhaps a little swollen, and covered with minute branny scales. Besides the thinly scattered long and healthy hairs are seen a number of broken stumps of hair, opaque, black or dark brown in colour, twisted and bent. By rubbing a patch with chloroform the stumps are rendered whitish and more easily visible. If an attempt be made to extract one of these broken hairs with a pair of forceps, it will almost certainly break off short ; if then moistened with a drop of liquor potassæ and placed under the microscope, the condition is explained. The substance is quite opaque, the natural structure of the hair is unrecognisable, and the hair seems to be converted into a mass of fungus spores (conidia). This is, however, only a sheath of spores surrounding the hair, which is itself occupied chiefly by mycelium tubes running in a longitudinal direction. These may be more readily observed in hairs which are less completely diseased.

The patch spreads by the implication of hairs at its circumference, and fresh patches form in other parts of the scalp. As these enlarge they become more completely denuded of long hair, though they nearly always present a considerable quantity of the short stumps which have been described ; and these may be surrounded and mixed with scabs, crusts, or sebaceous matter, or with a fine whitish powder, of which probably the fungus elements form a part. The patches spread slowly ; some may heal in the centre as they extend at the edges ; or the patches may coalesce, and nearly the whole scalp may be affected. Sometimes, on the other hand, one or two patches persist, without improvement, but without spreading. The disease may last for years, but eventually dies out, and the hair is perfectly restored. There is rarely much inflammation ; but occasionally the hair follicles inflame, coalesce, and form a red or pink swelling which is soft and boggy to the touch, and discharges pus from a few points ; the hairs are loosened and fall out, and the patch may remain bald when the other parts of the scalp have recovered. The condition is called *kerion*.

Probably the fungus invades the hair close to the scalp, and pushes down towards the bulb. The hair in the follicle is thus weakened or destroyed, and as it is forced outwards by the newly formed epithelial plates, it breaks off. The newly formed epithelium is, in its turn, invaded as soon as it gets into the horny condition. It was shown by Sir Frederick Taylor and Thin that the fungus

only invades the hair itself, and cannot be found in the cells of the root sheath or in the structures of the hair follicle.

Recently the **diagnosis** of scalp ringworm has been rendered much simpler owing to the fact that hairs and scales, infected by ringworm fungus, fluoresce more brilliantly than normal hair or the scales of other diseases, such as pityriasis simplex or psoriasis, when exposed to ultra-violet rays of wavelengths between 3,600 and 3,300 Ångström units. These are obtained by filtering light from a mercury-vapour lamp through Wood's glass. Exposure of an infected scalp to the rays in a dark room will cause the hair and scales on the areas involved to fluoresce with a brilliant green tint. By this method not only can early cases be detected with ease, but it can also be utilised to determine whether a child is cured after treatment, previously a difficult problem.

In this country ringworm of the scalp is due to the *Microsporon audouini* in about 90 per cent. of cases. It occurs almost exclusively in children and dies out spontaneously at puberty; a few cases have, however, been reported in adults. In other countries trichophytic or large-spored ringworm of the scalp is commoner, and this is seen both in children and adults; moreover, microsporons of animal origin, usually the *M. felineum*, may invade the adult scalp, as in the case of an elderly woman, seen by the writer, in whom infection had occurred from a Persian kitten.

The clinical appearances of ringworm of the scalp due to infection with a *Trichophyton endothrix* differ from those of microsporiasis. Two types of the disease are met with: (1) The infected hairs, intermingled with normal long hairs, are greyish, and broken off at a distance of 2 to 4 mm. from the scalp, the surface of which is covered with dry or greasy scales, containing twisted stumps of diseased hairs. This variety is due to the *Trichophyton crateriforme*. (2) The affected areas are studded with black points formed by infected hairs which are broken off level with the scalp or twisted on themselves in the mouth of the follicle. This is the "black-dot" ringworm of English writers. It is due to the *Trichophyton acuminatum* or the *Trichophyton violaceum*. The broken hairs, extracted with a needle from their follicles and examined microscopically, will reveal masses of large spores lying in the substance of the hair (endothrix).

Infection of the scalp with the endothrix fungi much more easily escapes recognition than microsporiasis, owing to the absence of definite scaly patches of some size, and to the fact that the infected hairs are intermingled with normal ones. Moreover, the stumps do not fluoresce with Wood's Light. Confusion with alopecia areata is also more likely to arise than in microsporiasis.

Ectothrix trichophytosis of the scalp may be contracted from animals, and almost invariably results in kerion, which undergoes spontaneous cure.

Tinea circinata, or ringworm of the glabrous skin, is met with (1) in children with *Tinea tonsurans* and those in contact with them, the fungus responsible being usually the *Microsporon audouini* or a *Trichophyton endothrix*: (2) in children without ringworm of the scalp and in adults, who have contracted the disease either directly or indirectly from infected animals. The fungus is then often of the ectothrix variety, but cases are now commonly met with in which the *Microsporon felineum*, contracted as a rule from blue Persian kittens, is responsible, and, as has been said, this may involve the scalp even in adults.

The clinical features of a patch of *Tinea circinata* depend to some extent on the species of fungus, the ectothrix varieties causing more intense inflammation than the others. The latter give rise to erythematous scaly lesions, almost exactly circular in contour with sharply defined edges. The patches spread at the periphery, and tend to heal spontaneously in the central parts, which therefore appear depressed in contrast with the raised margin; in this way the circinate configuration, from which the disease derives its name, arises. Very often vesicles or pustules appear, and are usually situated just inside the spreading edge, but may occur elsewhere; occasionally concentric circles of vesicles are

met with. The ectothrix fungi cause a severe inflammatory reaction, the patches being bright red, œdematous, and covered with vesicles and pustules, which dry up to form sero-purulent crusts.

The evolution of the lesions is rapid, and the size which they attain varies from that of a two-shilling piece to that of the palm of the hand. By confluence of adjacent patches polycyclical figures may result. The diagnosis of *Tinea circinata* should always be confirmed by examining microscopically scrapings from the edge of a patch or the roofs of the vesicles, soaked in liq. potassæ. The mycelium will be seen as branching, wavy lines, which must not be confused with the outlines of the horny cells. At a certain focus they have a greenish tint, and transverse septa, granules and vacuoles may be recognised; apart from the mycelia, groups of refractile spores are seen.

Tinea marginata (*Tinea cruris*, *Eczema marginatum*, or *Burmese Ringworm*). This form of ringworm, due to the *Epidermophyton inguinale*, of which at least three varieties exist, is very common in tropical countries, where it is known as dhobie (washerman's) itch, owing to the fact that it often results from infection of the underclothing during washing. It occurs chiefly in the groins, but may also involve the axillæ, and may spread from the groins backwards over the perineum and buttocks and upwards over the lower part of the abdomen. It may begin like an acute intertrigo, but more commonly the primary lesions consist of a few circinate patches, which coalesce to form red symmetrical, semi-circular areas, with sharply defined and slightly raised edges, on the inner surfaces of the thighs and the contiguous parts of the scrotum. As the disease spreads at the margins, recovery tends to occur in the centre. The lesions are much more extensive, more inflamed, and more obstinate than those of *tinea circinata*. The disease has become much commoner in England of late since the War, and it often occurs in epidemics in schools, colleges, and other institutions. The usual source of infection is doubtless the water-closet seat.

The epidermophyton fungus is also responsible for a very important condition known as *eczematoid ringworm of the extremities*, in which the infection involves the toes, the soles, the fingers, the palms, and sometimes the nails. On the feet it usually begins as indolent, scaly patches between the toes, spreading outwards on the lower and sometimes the upper surfaces towards the heads of the metatarsals; the edges consist of the raised horny layer, while the skin within them appears reddened and glazed or actually raw. Frequently eczematous vesicles are formed, so that the condition resembles pompholyx, and sometimes recurrent acute attacks of eczema occur, usually in hot weather, with much inflammation and the formation of numerous vesicles and bullæ. Secondary streptococcal infection may result, and lead to lymphangitis spreading up the leg. Most cases of so-called intertrigo of the toes, and many cases of eczema of the feet, are really examples of eczematoid ringworm, and in a doubtful case the under-surfaces of scales from the margins of the patches and the roofs of vesicles should be examined under the microscope for the fungus. On the hands the disease may resemble an erythemato-squamous eczema of the palms, or it may occur at the roots and sides of the fingers, as on the toes, and may spread upwards to their dorsal surfaces. Acute attacks resembling pompholyx are not infrequent, especially in hot weather. These vesicular lesions may contain the fungus in a state of active growth, or they may represent an eczematoid reaction of the epidermis to the fungus elements or toxin (epidermophytin) absorbed into the circulation from a site of active infection, and reaching distant parts of the skin through the blood stream (eczematoid epidermophytide). Thus recurrent attacks of such vesicular lesions on the fingers and palms are common in association with chronic epidermophytosis of the feet. Moreover, eczematoid patches of the nummular type, usually situated on the ankles and legs, may be due to the same cause. In these cases the epidermis is sensitised to the toxin of the fungus, and, if an intradermal injection of trichophytin or epidermophytin be

made into an unaffected part, *e.g.* the anterior surface of the forearm, an erythemato-urticarial reaction will arise at the site of injection within twenty-four hours, which may be replaced by an eczematoid reaction after an interval of a few days. Focal reactions in the existing eczematoid lesions may also occur. It is to the researches of Whitfield and Sabouraud that we owe the recognition of the parasitic origin of this form of eczema of the hands and feet, and the discovery is of great importance, since many unrecognised cases have been, and still are, treated for years as gouty eczema, or intertrigo, or pompholyx.

Tinea sycosis (*Ringworm of the beard, Hyphogenic sycosis*). The hair follicles of the chin and cheeks are here inflamed by the presence of the fungus; they suppurate, and the hairs become loosened. Induration and swelling of the intermediate skin also occur. It differs from sycosis, described elsewhere, in that it first attacks the hairs, and loosens them early, so that their extraction is painless; it spreads more rapidly and produces deeper infiltration. Microscopical examination shows the fungus, in which the mycelium is more abundant than the spores.

Tinea of the nails. The invasion of the nails by a fungus is called *onychomycosis*, and this may be a ringworm or favus. The nail becomes elongated and curved over the end of the finger, with a thick edge, rough, uneven surface, and dirty yellow colour; it is also brittle and readily splits. If fragments or scrapings are soaked with liq. potassæ, and examined under the microscope, branching mycelium and chains of spores of the fungus are seen.

Treatment. *Tinea tonsurans*. Two methods are commonly used:—

(1) Röntgen Rays. These have to be applied with great care and precision in order to avoid injuring the skin, and at the same time to get the full depilatory effect at one sitting. For this purpose the duration and strength of the application can be regulated by *Sabouraud's pastilles*, which are discs of paper thickly coated with an emulsion of platino-cyanide of barium. If the source of the rays is placed 15 cm. from the scalp, and the pastille exactly midway between them, *i.e.* 7½ cm. from the anti-cathode, the desired amount of influence is reached when the pastille acquires a particular fawn tint identical with a test colour supplied. The application is made to a limited area of the scalp at one time, the rest being protected by sheet lead; but time is saved by treating on the same day five points, situated at least 5 inches from one another. After fifteen to twenty days the hair comes out with the slightest traction; and the patch must be constantly washed with soap and water till it is all removed, the diseased hairs falling last. An antiparasiticide, *e.g.* ung. hydrarg. ammon., should be applied to the whole scalp during the defluvium. The head remains bald for five or six weeks, when finer and coarser hairs begin to grow.

(2) Epilation by Thallium Acetate. It has long been known that thallium acetate, given by mouth in sufficient dosage, causes the hair to fall out, and this action of thallium in *tinea tonsurans* has had considerable vogue as a substitute for radiotherapy. The dose of the drug recommended is 8 mgm. per kilo body weight, and owing to its toxicity, the most careful precautions must be taken to avoid an overdose. It is given in a small quantity of sweetened water in a single dose. At the end of a week the hair begins to loosen, and by the nineteenth day epilation is usually complete. The infected hairs fall less readily than the non-infected, and it is advisable to aid their removal by applying adhesive strapping and then forcibly pulling it away. It is also necessary to apply some antiparasiticide to the whole scalp in order to prevent reinfection of the new hair. Buschke advises the use of a 10 per cent. sulphur ointment from the first day of treatment until the hair falls, and then this ointment and tincture of iodine are applied on alternate days. The new hair grows more rapidly than after epilation by X-rays, probably owing to the fact that thallium, apart from causing the hair to fall, also stimulates its regrowth. The loss of hair produced by the drug has been shown to be due to failure of the process of transition from the

large polygonal cells to the stratified keratinised cells forming the hair. This method of epilation is suitable for the treatment of scalp ringworm in young children in whom the dosage, relative to body weight, would appear less dangerous than in older children. In the latter toxic symptoms are very likely to arise. Of these the commonest are joint pains, which usually begin early in the second week after administration, loss of appetite, irritability, drowsiness, and dryness of the skin. Albuminuria has also been noted. Unfortunately, errors of dosage have been made in some cases with disastrous results. It may be said that the treatment is practically free from risk in children under six years of age provided that (1) the drug is as pure as possible, (2) the child is accurately weighed naked, and (3) the dosage is most carefully checked.

Kerion. Suppurating ringworm of the scalp should never be treated by X-rays or thallium, as it tends to undergo spontaneous cure. Mild antiseptic compresses should be employed, and intramuscular injections of turpentine (*e.g.* *Terpichin*) or Aolan may be given to hasten resolution of the patches.

Tinea circinata is easily cured by the use of ung. hydrarg. ammon., oleate of mercury, tincture of iodine, sulphurous acid in solution (1 part to 2 or 3 of water), a weak carbolic acid glycerine, hyposulphite of sodium (1 in 8), or some other not too strong parasiticide.

Tinea marginata. Treatment of epidermophyton infection of the groins is usually not very difficult, but relapse will probably take place unless it be thoroughly carried out, and the underclothing be disinfected. For most cases the following method proves successful: The infected regions are sponged twice daily with a lotion consisting of 2 per cent. of salicylic acid in 75 per cent. spirit; at night-time the following ointment is thoroughly rubbed in: *R.* *Acidi benzoici* gr. xxv, *acidi salicylici* gr. xv, *paraffini mollis* \mathfrak{z} ij, *ol. cocois nuciferæ* ad \mathfrak{z} j (Whitfield); in the morning either the ointment is again applied, or the following dusting powder used after sponging with the lotion: *R.* *Acidi salicylici* 4 parts, *acidi borici* 20 parts, *talc.* to 100 parts. It is preferable that the patient should wear a pair of short cotton pants under his ordinary ones during treatment, and, even after apparent cure, the use of the lotion and powder should be continued for a week or so. In resistant cases *chrysarobin* ointment may be used, or the *pigmentum chrysarobini* B.P.C., but great care must be taken not to irritate the scrotum.

Epidermophytosis of the Extremities. This condition is usually most resistant to treatment owing to the thickness of the horny layer on the hands and feet, and the liability of reinfection from the nails. The methods employed must to some extent be varied according to the individual patient, but the following has given the writer good results in uncomplicated epidermophytosis of the feet. For about a fortnight a strong salicylic lotion (*R.* *Acidi Salicylici* \mathfrak{z} i, *Spt. vini meth. ind.* ad \mathfrak{z} i) is applied thoroughly between the toes and on other affected parts morning and evening, and after each application the *Pulv. Acidi Salicylici* Co. B.P.C. is sprinkled between the toes and in the socks or stockings. This treatment causes massive exfoliation of the infected horny layer, and, when this appears complete, the following method is substituted. At night time the above benzoic-salicylic ointment is rubbed thoroughly between and under the toes and on other affected areas, a pad of lint being used owing to the risk of infecting the fingers. White cotton socks are worn during the night. In the morning the feet are washed, and as much horny layer as can be easily detached is removed mechanically. They are then painted thoroughly with:—*R.* *Tinct. Iodi mitis* 1·0: *Spt. vini meth. indust.* ad 3·0, and the *pulv. acidi salicylici* comp. B.P.C. is dusted between the toes and into the socks. This treatment is carried out for a month, and the powder alone used for the next three weeks. The full treatment is then resumed for another month, and afterwards the patient is advised to use the powder for the rest of his life as a routine during the daytime. The socks should be washed by themselves and boiled with soda during the treat-

ment, and the shoes periodically swabbed out with pure lysol or cyllin. For the hands, the ointment may be applied under cotton gloves during the night, and the iodine painted on in the morning.

In cases with marked eczematization it is advisable to begin treatment with small fractional doses of X-rays before instituting one or other of the above methods.

Tinea barbæ (T. sycosis). The treatment is similar to that of kerion of the scalp (q.v.).

In *onychomycosis* the nails should be scraped thin, softened with alkaline solutions, and soaked in lotions of sulphurous acid, sodium hyposulphite, or mercury perchloride (2 grains to 1 ounce of water), or they may be frequently painted with carbolic acid. The better and quicker method is to remove the nails under an anæsthetic, and dress the nail bed continuously with iodine until regrowth has occurred.

Trichophytides, Microsporides, Epidermophytides, Favides. Comparable to the tuberculides is a group of eruptions associated with infection of the skin by various species of ringworm fungi; their occurrence depends on sensitisation of the skin as a whole to the antigen contained in the fungi and, as a rule, on entry into the general circulation either of the fungus elements themselves, or of the antigen-containing substance (trichophytin, microsporin, etc.). It is possible that, when the eruption is localised to the neighbourhood of the primary site of infection, contact of the antigen with the sensitised skin may occur, not through the blood-stream, but by external auto-inoculation, or *via* the lymphatics. These allergic fungus eruptions are most commonly met with in the suppurating forms of trichophytosis (trichophytides) and in epidermophytosis. Microsporides are rare, except in children with microsporon infection of the scalp, in whom the application of X-rays for epilation may result in a temporary acute inflammatory reaction. Favus is, of course, now very uncommon in this country, but favides, similar to the usual lichenoid trichophytide, have been described as occurring, particularly after X-ray treatment of the scalp.

The vesicular eczematoid epidermophytide has already been described. The following varieties of trichophytides have been recognised: (a) *The Papular Lichenoid Trichophytide* (lichen trichophyticus). This is by far the commonest, and is comparable to lichen scrofulosorum. The lesions consist of flat or conical papules, usually follicular, reddish or brownish in colour, and sometimes capped by a scale or tiny pustule. Like lichen scrofulosorum, they tend to be grouped, and appear chiefly on the trunk and limbs, rarely on the face. The follicular lesions may develop horny spines (one variety of lichen spinulosus). A corymbose form of the eruption has been described by Jadassohn and Sæves, similar to a corymbose syphilide. (b) *The Vesicular and Pustular Trichophytides*. (c) *The Eczematoid Trichophytide*. This is merely a variety of the lichenoid type, in which the lesions are closely set, and form scaly confluent patches, similar to the eczematoid tuberculide (dermatitis scrofulosa). (d) *The Scarletiform Trichophytide*. A generalised erythematous rash, resembling that of scarlet fever, accompanied by fever, enlargement and even suppuration of the lymphatic glands, may rarely precede the development of a papular or papulopustular trichophytide. (e) *The Nodular Trichophytide*. Several cases have been described with severe kerion, in which, in addition to a lichenoid trichophytide, subcutaneous nodules, like those of erythema nodosum, appeared. In Brüsgaard's case the fungus was actually found microscopically in the nodules and cultivated from them (26). (f) *Erythema multiforme trichophyticum*. This is the rarest of all, but authentic cases have been described.

In most cases of trichophytosis the local infection is not severe, and there is little or no constitutional reaction; careful examination of the trunk and limbs may reveal a lichenoid trichophytide, which has usually escaped the notice of the patient. In some cases, however, both the primary local inflammation and

the general symptoms may be intense. There is suppuration with surrounding œdema of the initial lesion, enlargement of the neighbouring lymphatic glands, which may suppurate and break down, pyrexia, generalised adenitis, a palpable spleen, swelling of the joints, a polymorphonuclear leucocytosis, and an extensive eruption of one or more of the trichophytides.

Pathology. A great deal of experimental work has been done in order to determine the exact pathogenesis of these eruptions. Neisser and Plato, in 1902, prepared an extract from ringworm fungi, which they named trichophytin, and which is analogous to tuberculin. In persons with the deep, suppurative type of ringworm, injection of trichophytin produces general and focal reactions, as does tuberculin in tuberculosis, and with it positive cutaneous and intracutaneous tests are obtained, which indicate a specific general allergic state of the skin; this state persists for years after the infection is cured. Normal controls and those with the *superficial* forms of ringworm give negative reactions. Apart from a general and focal reaction, injection of trichophytin may provoke an outbreak of a trichophytide eruption. Experimental inoculation of the skin of animals, *e.g.* the guinea-pig or rabbit, with certain ringworm fungi (*Trichophyton gypseum*, *Achorion quinckeanum*) produces lesions which heal spontaneously, leaving a lasting cutaneous allergy that prevents further successful inoculations, or at any rate, causes the secondary lesions to be short-lived and abortive. The same is true in human beings, for a deep-seated trichophytosis confers immunity in the sense that second attacks are very rare; this, however, is doubtless due to the allergic state of the skin leading to the rapid destruction of the re-inoculated fungus, rather than to true immunity (*cp.* Koch's phenomenon in tuberculosis).

It has been shown by Bloch, first, that animal immunity to ringworm can only be produced by inoculating the skin, subcutaneous or intraperitoneal inoculations being ineffective; secondly, that in a sensitised person the sensitiveness is in the skin cell itself, for by transplanting two pieces of skin, one from a sensitised and one from a non-sensitised person, on to a normal person, the piece from the sensitised person, after the graft had healed, gave a positive cutaneous reaction to trichophytin, whereas the other piece and the subject's own skin gave negative results. That in cases of trichophytosis with trichophytide eruptions the fungus elements pass into the general circulation is certain, for positive blood-cultures have been obtained, and the severer forms of trichophytide, *e.g.* the nodose variety, are probably caused by actual embolism of these in the dermic or subcutaneous vessels, and their rapid lysis by the sensitised skin, with liberation of the antigenic substance. Bloch, however, produced a scarlatiniform erythema, and later a typical lichenoid trichophytide, by injection of trichophytin in a boy who had had a severe ringworm infection but was cured. It is possible, therefore, that the milder trichophytides are due to absorption of the antigenic substance from the primary site of infection, and not to the hæmatogenous spread of the actual fungus elements.

We thus see how closely in their pathogenesis the syphilides, tuberculides, and trichophytides are related. These infections may result in a high degree of allergy, whereby the tissue-cells, particularly of the skin, become sensitised, so that, when the dissemination through the blood-stream of the infective organism, or, in some cases, of its toxin, *e.g.* tuberculin and trichophytin, takes place, a variety of eruptions—or cuti-reactions—occur, representing defensive reactions against superinfection, and resulting in the destruction of the organism or toxin *in situ*. Recently eruptions comparable to the trichophytides, but chiefly of the maculo-squamous or eczematoid type, have been described in connection with *Monilia* infections (levurides).

TINEA VERSICOLOR

This is a common affection of the skin, produced by contagion, and fostered by warmth and moisture. It is more frequent in men, and especially in those

who wear flannel underclothing. It is not often conveyed directly by contact—for instance, from husband to wife.

The disease begins as a small circular spot, of a yellowish-brown colour, which is slightly raised above the skin, and from which a few whitish scales can easily be detached by scraping with the finger nail or a scalpel. The patches extend, and fresh ones form, so that soon a large part of the chest, where it is commonly seen first, is covered with a brown or brownish-yellow irregular patch, with a convex or scalloped margin; and on the healthy skin adjacent are numerous small isolated patches from $\frac{1}{4}$ to $\frac{1}{2}$ inch in diameter. The disease occurs only on covered parts, and is most abundant on the front and back of the chest and the abdomen. The scrapings examined in liquor potassæ under the microscope show epithelial plates with the specific fungus, *Microsporon furfur*, forming a network of branching mycelial threads, scattered among which are little groups of the relatively large conidia, like bunches of grapes. The affection does not cause much trouble beyond some itching, and is frequently ignored by the patient; but the great extent which the discoloration may sometimes reach has led to its being mistaken for Addison's disease and other pigmentary affections such as vitiligo. The peculiar colour, the convex edge, and the ready desquamation of the surface should be quite distinctive, and the diagnosis is at once confirmed by the microscope.

Treatment. It is quickly cured by rubbing in lotions of sodium hypsulphite (1 in 8) or of sulphurous acid (1 in 4), or a paste containing sulphur, resorcin, and salicylic acid. It may, however, return if the same underclothing is used without thorough washing and disinfection.

Erythrasma. This eruption is most commonly seen in adult or aged men of all social classes; it is rare in women and never occurs in children. It causes no inconvenience, apart from slight itching after sweating, and is often discovered accidentally. Its site of election is the genito-crural fold and the inner surface of the adjacent portion of the thigh; it seldom invades the scrotum or pubis, but may rarely occur in the axillæ. It consists of brownish or yellowish-rose patches, hardly raised above the surface of the skin, slightly scaly, and never vesicular; the margins are sharply-defined but, unlike those of tinea cruris, are not raised. Occasionally outlying oval patches are seen on the abdomen and thighs. The disease is only slightly contagious.

The cause is an infection of the horny layer with the *Microsporon minutissimum*, the mycelium of which is very fine and the spores very small. It may be seen by examining scales in liq. potassæ with a $\frac{1}{2}$ -inch oil-immersion lens.

The differential **diagnosis** from tinea cruris is not difficult, since the latter is redder in colour, has raised edges, tends to spread down the thighs and on to the scrotum and pubis, is often vesicular, and has a much more rapid evolution. Intertrigo due to streptococcal or Monilia infection is more inflammatory and usually moist. **Treatment.** Whitfield's benzoic-salicylic acid is effective, but must be used for a considerable time to prevent relapse.

Lepothrix (*Trichomycosis palmellina*. *T. nodosa*). This condition is met with all over the world, usually in those careless of their personal cleanliness. It affects the hairs of the axillæ and pubis, which become surrounded with yellowish, reddish or black concretions, usually forming irregular nodules along the shafts. These are seen microscopically to consist of masses of micrococci, embedded in a homogeneous viscid substance. According to Castellani, the yellow variety is due to a fungus, *Nocardia tenuis*; the red to the same fungus in symbiosis with a red pigment-producing coccus; and the black to the nocardia with a black pigment-producing coccus. Most cases of so-called chromidrosis are due to lepothrix.

Treatment. The affected parts should be cleaned with benzine, and then swabbed with an alcoholic solution of perchloride of mercury (1/2000), or of formalin (2 per cent.). It may be advisable to shave the hair.

Oïdiomycoses During recent years the importance of yeast-like organisms in the causation of certain dermatoses has become increasingly recognised. The pityrosporon of Malassez, which belongs to this group, has already been described. The exact classification of these organisms is difficult, and will not be discussed. They resemble yeasts in that they are round or oval and multiply by budding, but belong to a lower order and are classed as fungi imperfecti. One family, the *Cryptococcaceæ*, includes the genera *cryptococcus*, *torula*, and probably *pityrosporon*. Another, the *Oösporaceæ*, includes *oöspora*, *oïdia*, and *monilia*. The latter form long and branched mycelia when growing in the skin, the former do not. Apart from the pityrosporon, most of the pathogenic organisms so far investigated belong to the genus *Monilia*, of which the thrush fungus, *M. Albicans* and *M. pinoyi*, are the most important.

The types of eruption caused by *Monilia* may be classified in the following way (27): (1) *Generalised Type*. This is met with chiefly in patients undergoing treatment by the continuous bath, which is employed principally in Vienna. The lesions consist of vesicles, papules, and scaly erythematous patches, and involve particularly the axillæ, knees, and hands: but the eruption may be widespread. (2) *Infantile Type*. This is seen in nursing infants, and is often associated with thrush of the mucous membranes (*q.v.*). The eruption usually appears first around the anus, and spreads over the buttocks, genitals, thighs and abdomen, whence it may extend to the axillæ, neck and face. It is composed of vesicles, pustules, and erythematous plaques with central scaling; the vesicles and pustules rupture, leaving a fringe of horny layer, from which the infection may spread to form erythematous-squamous patches with raised borders. This type may complicate the infantile erythema of Jacquet. (3) *Intertriginous Type*. This is the commonest type of all, and has to be distinguished from intertrigo due to streptococcal or ringworm infection. It is seen in the groins, the internatal cleft, the axillæ, under the breasts in women, and in the hypogastric fold of obese persons. The eruption involves chiefly the areas in which the opposing surfaces of skin are in contact, forming scaly patches or superficial erosions with a collarette of undermined horny layer at their edges, but outlying erythematous-squamous lesions also occur. (4) *Interdigital Type*. Formerly known as "erosio interdigitalis blastomycetica," this type is met with most commonly in those whose hands are constantly wet, *e.g.* washerwomen and bar-tenders. The third interdigital space is most likely to be affected. The eruption begins as groups of vesicles, which rupture leaving a raw surface with a margin of thick sodden epithelium. (5) *Infection of the Nails*. Various forms of onychia or paronychia, due to *Monilia*, have been described. Subungual abscesses and hyperkeratosis of the nail-plate occur, but more characteristic is a paronychia, in which the nail-fold becomes very swollen over a considerable area. Recurrent acute attacks of inflammation with periods of remission are the rule. The nail-plates become dystrophic.

Apart from these types of *monilia* infection, the writer has met with chronic cases of eczematoid and intertriginous dermatitis of the hands and feet, resembling eczematoid ringworm, due to this organism. They are often extremely resistant to treatment.

Diagnosis. Microscopical examination and cultures are necessary to establish the diagnosis. In potash preparations the mycelia are seen to be long, thin, non-septate as a rule, and with short lateral buds; with them occur numerous groups of spores. On culture the organism grows in profusion and usually in pure culture, which is not the case if it be merely a saprophytic contamination.

Treatment. Surface infections with *monilia* may usually be treated successfully by painting with dilute tincture of iodine, or by rubbing in the benzoic-salicylic ointment recommended for epidermophytosis. More effective, perhaps, is a 2 to 3 per cent. solution of gentian violet in 25 per cent. spirit. For the paronychia, pure carbolic acid or undiluted monsol is applied beneath the

raised nail-fold on cotton-wool, twisted around a match-stick sharpened flat, and swept from side to side. With Monsol the applications can be made daily, with carbolic acid every four or five days.

Spirochætal Diseases

Syphilis	Treponema pallidum (p. 104).
Frambœsia (yaws)	Treponema pertenue (p. 1030).

VENEREAL WARTS

(*Condyloma vel verruca acuminata*)

Venereal warts are seen in both sexes. In men they occur chiefly in the furrow behind the glans penis, and on the corona and frenum, but may involve the whole prepuce and even the urethral orifice. In women they are seen on the vestibule, the fourchette, and the clitoris, and may spread over the whole vulva to the groins, anus, and perinæum. Rarely they are met with in the axillæ and on the scalp.

They consist of papillomatous vegetations, pink or brownish-red in colour, sessile and lobulated, or filiform and elongated. In women they may form enormous cauliflower-like masses, moist and foul-smelling. Being auto-inoculable, they tend to involve contiguous surfaces.

Ætiology. Favre and Civatte have shown that the causal organism is almost certainly a spirillum, which is found in large numbers, both extra- and intra-cellularly. Lack of personal cleanliness, moisture, heat, and irritating discharges, which macerate the epidermis, favour their development. Gonorrhœa is a frequent though not essential predisposing cause, and pregnancy would seem to be a factor of importance.

Anatomy. The vegetations consist of filiform outgrowths of young connective tissue, containing numerous large blood vessels, and covered by a thickened, actively growing Malpighian layer, the cells of which are in a state of rapid multiplication. The horny layer is thinned.

Treatment. Scrupulous cleanliness, and the use of astringent lotions and a dusting powder, containing salicylic and boric acids, may cause their disappearance. In resistant cases the X-rays should be employed, or the vegetations may be removed with a curette.

Protozoal Diseases

Leishmaniasis (oriental sore)	Leishmania (p. 1052).
Amœbiasis.	Entamœba histolytica (p. 1056).

Amœbiasis of the skin was first described by Engman and Heithaus in a child suffering from amœbic dysentery, and must be excessively rare.

Metazoal Diseases

Various animal parasites may infest the human skin, and give rise to lesions or eruptions, which are, as a rule, characteristic. Lice, fleas, bugs and mosquitoes are examples of parasitic insects; several varieties of acarus, e.g. the *Sarcoptes scabiei hominis*, the cause of human scabies, the *Leptus autumnalis* or "harvest bug," the *Ixodes ricinus* or "wood-louse," the *Pediculoides ventricosus*, the cause of "grain-itch," and the varieties of *Sarcoptes*, parasitic on animals such as the dog, cat, sheep, and pig, may all invade human beings. Lastly, certain worms and larvæ may enter the skin, e.g. the guinea-worm, the larva of *anchylostoma duodenale*, and the larva of certain dipterous insects—*larva migrans*.

The pediculi or lice which infest the human race are of three species: *Pediculus capitis*, or head louse; *P. corporis*, vel *vestimentorum*, or body louse; and *P. pubis*, or crab louse.

PEDICULUS CAPITIS

The head louse is about 2 mm. long by 1 broad, and breeds amongst the hairs of the scalp. It is of a greyish-yellow colour, and there are black marks on either side at the junctions of the seven abdominal segments. Its ova are found adherent to the hairs and are called nits. They are about $\frac{1}{2}$ mm. in length, whitish, somewhat conical in shape, with the apex always towards the scalp; and they are fixed to the hair by a cylindrical sheath of chitinous material extending some little distance beyond the apex. The irritation of the pediculus leads to constant scratching and pustular eczema, or contagious impetigo. This eruption is most common and severe in the occipital region, and the suboccipital glands are often enlarged as a consequence, and may suppurate.

The **Diagnosis** is not difficult. If the pediculi are not at once seen, the nits, which are readily distinguished on careful examination from scurf, will show at once that there are or have been pediculi. The position of the crusts at the back of the head is also strongly in favour of pediculi.

Treatment. The parasites are rapidly destroyed by vaseline, which blocks their respiratory tubes, or by benzol. Sabouraud recommends a mixture of 50 drops of xylol and 50 grammes of vaseline. This is smeared thoroughly all over the head, and left on for twelve hours; the hair is then shampooed, and the nits removed by combing with dilute acetic acid. A solution of carbolic acid (1 in 40) is also effective; the hair should be saturated with it and wrapped in a towel for an hour or two before shampooing. The secondary impetigo may require treatment with mercurial ointments, but, as a rule, quickly disappears when the parasites are destroyed.

PEDICULUS VESTIMENTORUM (See Plate 59, B, p. 878)

The body louse is larger than the head louse, being nearly 3 mm. in length and from 1 to $1\frac{1}{2}$ mm. in breadth. It is of a light greyish colour, except when gorged with blood, which gives it a dark reddish hue. The abdomen, consisting of eight segments, has no black markings. The parasites infest the underclothing of the host, where they may be found in the seams. The ova are deposited in the clothing, but, as was discovered in the war, may be attached to the body-hair, particularly of the pubic region. The fecundity of the females is enormous, and Nuttall estimated that a single parasite during her lifetime produces 275 to 300 eggs, of which seventy are deposited daily. Body-lice can exist without food for three days, and are resistant to cold, but they are killed by a temperature of 80° C.

The bites of these parasites give rise to urticated papules, which are intensely itchy; lice appear to feed chiefly at night time, when, as in scabies, the irritation is most severe. In those persons who are chronically lousy, some tolerance is established, and, although they continue to scratch, little complaint of itching may be made.

As a result of scratching, *linear* excoriations are produced and correspond to the *lignes de grattage*. These are usually best seen over the shoulders. Secondary pyogenic infection is likely to occur, so that crusted impetiginous lesions, and the deep ecthymatous ulcers which complicated the severe cases of pediculosis met with in the war, may develop.

The deeper excoriations are succeeded by pale linear scars.

The sites of election of these various lesions are the shoulders, posterior axillary folds, the flanks, the sacral region and upper parts of the buttocks, and the anterior and outer surfaces of the thighs. In long-standing cases the skin becomes dry, harsh, scaly, and deeply-pigmented ("Vagabond's disease"). The pigmentation, accompanied by excoriations and their resulting scars, predominates on the sites of election, but may become generalised and so intense as to resemble that of Addison's disease. Moreover, it may be present in the

buccal mucous membrane, and, since severe pediculosis may produce asthenia and cachexia, the diagnosis from this disease may be difficult. The localisation of the pigmentation in the mouth and the asthenia suggest that the venom of the pediculi has a toxic action on the endocrine-sympathetic system, and it is of interest that during the war the writer observed several cases of vitiligo in which this pigmentary disturbance had evidently been provoked by pediculosis (28).

The main points in the differential diagnosis between pediculosis corporis and scabies (*q.v.*) are as follows :—

Pediculosis Corporis

Sites of election. Shoulders and posterior axillary folds, sacral region and upper parts of the buttocks, flanks, anterior and outer portions of the thighs.

Lesions. The *scratch-marks* are linear blood-crusts corresponding to the *lignes de grattage*.

Other lesions are urticated papules from recent bites; impetiginous and ecthymatous sores; and superficial linear scars.

Pigmentation of the sites of election is intense, and may become generalised.

It will be observed that the shoulders and back, which are the parts chiefly affected in pediculosis, are relatively spared in scabies. Apart from such conditions as obtain in an army on active service, pediculosis corporis is met with almost exclusively in old persons of both sexes, even those in comfortable circumstances, and in tramps. It has to be distinguished from true senile pruritus and from that dependent on metabolic disorders, *e.g.* hyperglycæmia and renal or hepatic insufficiency; nervous diseases, such as tabes dorsalis; psychological disturbances; and from the prurigo of lymphadenoma, leukæmia, and pregnancy. It should be remembered that typhus, trench and relapsing fevers are transmitted by lice.

Treatment. Ung. hydrarg. ammoniati or ung. staphysagriæ, smeared over the skin, will kill the pediculi. The clothes, in which the eggs are certainly incubating, should be completely changed; and they must be baked if they are to be worn again. The necessity of removing or destroying ova attached to the body-hair must be remembered. N.C.I. (naphtholine 96, creosote 2, iodoform 2) and pyrethrum powders have been used to prevent reinfection, but both may cause a severe dermatitis in certain subjects.

PEDICULUS PUBIS

The crab louse is smaller than either of the other species, measuring from 1 to 1½ mm. long, and from 1 to 1½ broad. It has an almost square body, and six long legs, with claws by which it clings firmly to the hairs of the part. It is not only found in the pubic and axillary hair, and in that over the sternum, but is occasionally conveyed to the eyebrows, eyelashes, whiskers, or beard. The eggs are attached to the hairs close to the skin. Itching leads to scratching, and an eczematous rash is the result. In many cases bluish-grey macules (*maculæ cæruleæ*, *taches bleues*, *taches ombrées*) about the size of a finger nail are seen in the skin of the lower abdomen and thighs, and on the sides of the thorax, if the axillary and thoracic hair is affected. They are absolutely characteristic of

Scabies

Fingers, anterior surfaces of the wrists, elbows, anterior axillary folds, nipples (in women), abdomen, lower parts of the buttocks over the ischial tuberosities, legs, ankles, and feet.

The *scratch-marks* are pin-point crusts situated at the apices of erected follicles.

Other lesions are burrows; vesicles and pustules; elongated and indurated papules in the anterior axillary folds, on the scrotum, and over the ischial tuberosities; eczematous, impetiginous crusts and boils.

Pigmentation is slight or absent.

crab-louse infection, though formerly they were thought to be symptomatic of typhus and even typhoid fever. The pigment in these macules is derived from the salivary glands of the louse.

Treatment. The unguentum hydrargyri B.P. is a favourite remedy among the public, and it is very effectual, but it is apt to cause pustular folliculitis or even acute mercurial dermatitis. A safer method is first to soak the infected parts for an hour with a solution of carbolic acid (1 in 40) applied on lint, and then to rub in an ointment containing yellow oxide of mercury, ammoniated mercury, or balsam of Peru for a few days. Benzol, or a mixture of benzol and xylol, kills the parasites instantly, and one thorough application suffices for cure, but it is advisable to employ a mild mercurial ointment afterwards lest some of the ova may have escaped destruction. The pubic hair need never be shaved. It should be remembered that, although infection usually takes place from sexual intercourse, it may be acquired in other ways, as from dirty closet seats.

SCABIES (See Plate 59, A, p. 878)

Scabies, or itch, is a multiform disease of the skin, consisting of papules, vesicles, pustules, and sometimes bullæ, due to the irritation of the itch acarus, *Sarcoptes hominis*.

The female acarus is oval in shape, $\frac{1}{10}$ inch in length, presents in front four little nipple-shaped processes provided with suckers on stalks, and behind four similar processes provided with long bristles. The male is smaller, has four suckers in front, two suckers and two bristles behind. The female after impregnation bores her way under the skin in an oblique direction, so that, as the superficial layers of the epidermis are detached by friction, she still remains at the same depth from the surface. As she proceeds she lays her eggs, one or two daily, it is said, and she may thus burrow through the skin in an irregular line for $\frac{1}{2}$ or $\frac{3}{4}$ inch. Such a burrow (*cuniculus*), or "run," may be recognised on the surface of the skin by the following features: At one end the epidermis is broken or frayed, and the free edges are dirty; at the other end is a minute white pointed elevation, in which the acarus lies; the burrow itself between these points is a sinuous black line. The whole burrow may be snipped off with a pair of scissors curved on the flat, or shaved off with a scalpel; and if it be then moistened with liq. potassæ and examined, there will be seen the female acarus, and behind her, filling the burrow, her eggs in every stage of incubation, with minute black spots of excremental matter among them. As the skin desquamates the most developed ova come to the surface, and are hatched. The male does not burrow, but remains on the surface, where he may be sometimes accidentally caught.

Symptoms. As a result of the invasion of the acarus there is considerable itching, with consequent scratching, pus infection, and dermatitis of variable extent and character. The itching is mild or severe, but not generally so bad as that caused by pediculi, and the scratching rarely leaves scars or causes pigmentation. It is worse at night when the patient is warm in bed. The disease causes erection of the pilo-sebaceous follicles, owing to contraction of the pilo-motor muscles, and their summits are excoriated by scratching, so that the scratch-marks consist of pin-point blood-crusts at the apices of the erected follicles, thus differing from the linear scratch-marks of pediculosis corporis. They are usually well seen on the abdomen and limbs. In many cases elongated inflammatory papules of considerable size, in which the acarus may be found to lie at some depth, are present. These are pathognomonic, and occur on the anterior axillar folds, the scrotum, penis, over the ischial tuberosities, and around the elbows. Their recognition is of great importance, since their presence clinches the diagnosis even when burrows cannot be detected. Apart from these there occur in the early stages erythematous and urticarial lesions, and later vesicles, pustules, impetigo, ecthyma, and eczematization; the last may be of the dysidrosiform type on the extremities, but elsewhere consists of crusted patches

of varying size. A vesicle or pustule may form at the extremity of a burrow where the acarus lies. Purulent bullæ are not uncommon on the palms and soles of young children. In women eczematization of the nipples and areolæ is frequent, and this is nearly always due either to scabies or lactation. A moderate degree of eosinophilia and occasionally a transitory albuminuria indicate that the acari, like *pediculi corporis*, produce a toxin which is absorbed.

Sites of Election. These various lesions occur principally in the interdigital spaces of the hands and on the lateral borders of the fingers; the palms; the front of the wrists, particularly on the ulnar side; the elbows; the anterior axillary folds; the nipples in women; the abdomen; the foreskin and glans penis; the buttocks; over the ischial tuberosities; the thighs; the ankles and toes; and the soles of young children. Burrows are most likely to be seen on the fingers, wrists, elbows, penis, and in children on the soles. It will be observed that the face, neck, shoulders and back are spared, but in infants the face and the posterior fold of the neck may be involved from contact with the mother's breasts and wrists respectively.

For contagion with scabies to occur it is essential that an impregnated female acarus should be transmitted from an infected person. This may result directly and almost inevitably from sharing the bed of a scabietic, thus accounting for familial epidemics, and for the frequency of a venereal origin of the disease. Indirect transmission through sheets and clothing often occurs, and commercial travellers, who are compelled to sleep in small hotels, where clean sheets are not always provided, are particularly liable to infection in this way. It is doubtful whether it is possible to contract the disease by ordinary contact with an infected person during the daytime, although nurses who tend scabietics confined to bed may do so.

Diagnosis. The position of the lesions is an important guide to diagnosis. An itching eruption of mixed papules, vesicles, and pustules, occurring mainly about the fingers and wrists, and also in the other situations mentioned, should lead to a careful search. If a burrow can be found, the minute white elevation at the cleaner end should be looked for, and its epidermis carefully scratched through with the point of a needle; the acarus may then be picked out, as it readily adheres to the surface of the needle. If this cannot be done, it is best to snip off the whole burrow, and to examine for ova or fragments of the acarus under the microscope. Finally, where there has been much inflammation, so that burrows cannot be found, the crusts may be removed, boiled in a solution of potash or soda, the fluid allowed to settle in a conical glass, and the sediment examined for fragments of acarus.

Treatment. The successful treatment of scabies depends upon the thoroughness with which it is carried out. It is useless to tell the patient to rub in sulphur ointment "where it itches"; it is essential that all infected members of a household should be treated simultaneously; and the patient should be warned that, if there is still irritation of the skin after the prescribed treatment has been thoroughly performed, it will almost certainly be due to the application employed and not to a persistence of the infection.

The following method is usually successful:—

(1) On the first night, the patient should take a prolonged hot bath lasting about twenty minutes, to which Sulphaqua may be added. In the bath the skin of the whole body from the neck downwards should be thoroughly scrubbed with soap in order to open up all the burrows.

After the bath, the following ointment should be rubbed in thoroughly all over from the neck downwards, not forgetting the fingers and toes:—

R. Sulph. præcip. gr. 30

Balsam Peruviani gr. 20

Ung. Zinci to the ounce.

and the patient should get into old pyjamas, cotton socks and gloves.

(2) On the next two mornings and two evenings, further inunctions with the ointment should be made.

(3) On the third morning, a second bath should be taken, and the patient should put on entirely clean underlinen. It is important that all used under- and bed-linen should be disinfected.

Instead of the above ointment, Mitigal (Bayer) or "Danish" ointment may be employed. It is claimed that a single application of the latter suffices. After the treatment, the patient should apply a soothing cream or a zinc paste for a while.

Norwegian Scabies. This variety was first described by Danielssen and Boeck among lepers. It is characterised by extensive encrustation sometimes involving the whole skin, including the face and back. The crusts are formed of dried pus and scales, and are riddled with burrows containing countless parasites and ova. The nails are distorted and disintegrated, and harbour the acari. The condition was formerly thought to be due to infection with the acarus of the wolf, but is now known to be human scabies occurring in destitute, neglected persons of low mentality.

Animal Scabies (Sarcoptic mange). The sarcoptes of animals (dog, cat, horse, camel, pig, sheep, goat) may be transmitted to human beings, but they never form burrows. The parts affected are those that have been in contact with the animal. The lesions produced are small papulo-vesicles, often surrounded by urticated wheals, and recall somewhat those of papular urticaria. They are intensely itchy. Severe cases of horse scabies in man have been described, the eruption resembling a generalised pityriasis rubra; innumerable parasites are found in the scales and crusts. As sarcoptes of animal origin do not burrow or breed in human skin, the disease is easily cured, a single inunction with sulphur ointment sufficing, providing the source of infection is removed or treated.

Grain-itch. This is an eruption consisting of urticarial wheals, with a central vesicle or pustule, which may become of considerable size and simulate the lesions of chicken-pox. Itching is intense, and there may be secondary pyogenic infection with slight pyrexia and malaise. A moderate leucocytosis and eosinophilia have been found. The eruption is caused by the *Pediculoides ventricosus*, which may infest straw and grain. It occurs in those who handle these, e.g. dock labourers and sailors, and infection from straw-mattresses has been recorded. The mite does not burrow, and is easily destroyed by sulphur ointment; the clothing should be baked or fumigated.

Copra-itch. An eruption resembling scabies apart from the absence of burrows, and due to the *Tryglyphus longior*, which is present in copra dust. It is treated with sulphur or beta-naphthal ointments.

The following Diseases are Classified according to their Morphology.

THE ERYTHEMAS

The classification of the eruptions to be considered in this second group is admittedly unsatisfactory. Many of them are merely forms of cutaneous reaction to a variety of toxic or irritant substances, either of exogenous or endogenous origin, for example, certain erythemata, urticaria and eczema, and are manifestations of an allergic state of the skin (cp. the tuberculides and trichophytides). Their morphological differences depend upon the particular elements in the skin that are sensitised rather than on the nature of the antigen. It might be preferable to attempt to classify together these non-specific allergic eruptions; such a group would include urticaria and angeioneurotic oedema, eczema, and certain prurigos, which are often associated or alternate with other allergic symptoms (see toxic idiopathies, p. 138), and some forms of generalised exfoliative dermatitis. In the present state of knowledge, however, it has been thought pre-

ferable to adhere to the morphological classification adopted in the previous edition.

There is little doubt that Erythema multiforme, *E. nodosum* and *E. scarlatiniforme*, particularly in their recurrent forms, may be due to sensitisation having occurred to some strain of a *Streptococcus longus*, and the same is probably true of some cases of Lupus erythematosus; but Erythema multiforme, Erythema nodosum, and Erythema scarlatiniforme may also be caused by sensitisation to a trichophyton, and Erythema nodosum, Lupus erythematosus and, perhaps, Erythema multiforme, may in some instances be tuberculides. Therefore, however unwilling one may be to ascribe eruptions with well-defined clinical characteristics to multiple causes, it must be accepted that these forms of erythema are syndromes, and not specific entities.

ERYTHEMA MULTIFORME (See Plate 58, B, p. 833)

Some authors are inclined to include under the heading of Erythema multiforme the ill-defined erythematous-urticarial rashes that may result from sensitisation to food-substances (*e.g.* pork, shell-fish), foreign serums ("serum rash"), various drugs, and many bacterial and protozoal toxins, but the classical form of the eruption known as *Erythema exudativum multiforme* is a clinical entity and should be separated from the above.

Symptoms. The eruption, which is often accompanied by sore throat, fever, pains in the joints and muscles, and gastro-intestinal disturbance, appears suddenly, at first almost invariably on the parts exposed to light, *viz.*, the backs of the hands and wrists, the face and neck, and, in women, on the V-shaped area of the upper chest exposed by the cut of the blouse. It is bilaterally symmetrical, and later may involve the forearms, elbows, knees, ankles and feet; occasionally it is more or less generalised. The *mucous membranes* of the lips, cheeks, tongue, pharynx, and vulva are frequently involved, particularly in the bullous form, and in recurrent cases. Moreover, the mucous membranes may alone be affected by periodical attacks for years without any cutaneous lesions developing, and many cases of so-called recurrent stomatitis are really of this nature.

As the name suggests, there is considerable variety in the lesions produced. The most characteristic, seen typically on the backs of the hands and wrists, are raised, flat, disc-like erythematous papules, bluish-red in the centre, bright red or pink at the periphery; on palpation such a lesion gives to the finger a peculiar sensation as of an india-rubber cap stretched over the mouth of a bottle full of water. The centres of the lesions are often white, owing to the exudation of fluid, which may be sufficient to produce a vesicle or bulla (*E. bullosum*), and in some cases large, pemphigoid bullæ, surrounded by an erythematous halo, occur; sometimes actual hæmorrhage takes place in the centre of a papule (*Purpura urticans*). Moreover, the central parts may clear, leaving rings (*E. annulatum*), which by coalescence produce sinuous or scalloped patches (*E. gyratum*). Rarely a ring of erythema is surrounded by another right outside it, and this is followed by another farther out, while the first ring is beginning to fade. The different colours of the rings in various stages suggest the name *E. iris*. As many as four such rings may be seen at the same time, sometimes arranged concentrically around a central bulla (*Herpes iris*), which may occasionally be surrounded by one or more rings of smaller bullæ or vesicles. On the mucous membranes the lesions consist of flaccid bullæ, which are rapidly replaced by extremely painful erosions upon which a diphtheroid membrane forms; in some cases practically the entire buccal and pharyngeal mucous membranes are involved, and the pain and discomfort are such as to render eating almost impossible.

One of the most striking features of erythema multiforme is its tendency to recurrence; these recurrences occur at varying intervals, sometimes annually—as a rule in the spring—, sometimes every two or three months, and rarely a new

attack may begin before the lesions of a previous one have disappeared. Osler long ago emphasised the close association that exists between erythema multiforme, urticaria, purpura and erythema nodosum, and their connection with visceral disease, such as endo- or myocarditis, nephritis, and gastro-intestinal disturbances. This association is easily explained, because one cause of E. multiforme, E. nodosum, and purpura is an acute or chronic streptococcal infection, and urticaria may be due to sensitisation to the same organism. Apart from true erythema nodosum, there may rarely be seen in association with the usual superficial lesions of E. multiforme circumscribed intradermic or subcutaneous nodules, doubtless caused by emboli of streptococci. Another eruption, which occurs so frequently with erythema multiforme, particularly of the recurrent type, that the association cannot be merely fortuitous, is herpes simplex. Several patients have been observed in which a tendency to recurrent outbreaks of the two eruptions has been present, over a long period, and in two under the writer's care injection of an emulsion of herpes virus apparently produced immunity of considerable duration to both.

Ætiology. As has been said, erythema multiforme, like urticaria and some other forms of erythema, even in its most classical form, cannot be regarded as an absolutely specific reaction. The work of Landouzy would seem to prove that it, as well as erythema nodosum, may be a toxi-tuberculide. As the result (29) of inoculating guinea-pigs in series with blood taken from four cases during the attacks, Ramel concludes that the eruption is due to a tuberculous bacillæmia, and he considers that a preceding streptococcal infection, such as tonsillitis, is merely a provoking factor. His findings, however, have not been confirmed in this country (30). An erythema multiforme type of trichophytide has also been described, but in the great majority of cases erythema multiforme is probably due to sensitisation having occurred to a strain of *Streptococcus longus*. Its association with acute rheumatism is too frequent to be a coincidence; it occurs in streptococcal septicæmia, and an attack may usher in a fatal streptococcal infective endocarditis. In a series of patients subject to recurrent attacks one or more foci of chronic streptococcal infection were invariably found, specific agglutinins and precipitins were present in the serum, injections of a vaccine prepared from the infecting strain of streptococcus often provoked focal reactions, *i.e.* the appearance of a few typical lesions on the skin or mucous membranes, and removal of accessible foci of infection, combined with the administration of an autogenous streptococcal vaccine over a long period, brought about a cessation of the attacks (31). The usual sources or portals of entry of infection are the tonsils, nasopharynx, teeth, nasal sinuses, and intestines, but possibly others, such as the prostate and cervix uteri, may be responsible. It is possible that in some cases erythema multiforme may be a widespread cutaneous reaction to invasion with the virus of herpes simplex. Exposure to sunlight is undoubtedly a factor in predisposing to an outbreak of the eruption and in determining its localisation.

Treatment. The patient should be put to bed, and the heart watched carefully for signs of endocarditis or myocarditis. Sodium salicylate or salicin, combined with alkalis, may be given, or quinine. Locally cooling lotions, such as lotio plumbi or lotio calaminæ, should be applied during the acute stage. In the bullous form of the eruption, when the mucous membrane of the mouth is involved, the pain and discomfort may be relieved by allowing the patient to suck the trochiscus krameriæ et cocainæ B.P. and the trochiscus acidi carbolicus B.P.

When the attack has subsided, a search should be made for some chronic focus of infection, such as the tonsils or teeth, and, if found, this should be dealt with. In recurrent cases a streptococcal vaccine, prepared from the infecting focus, and preferably injected intradermally, should be administered over a long period. For the anæmia, following the attack, iron should be given until the blood returns to normal.

Erythema Annulare Centrifugum. Numerous observers have described under various terms circinate or figurate erythematous eruptions, but these may be included under the descriptive title erythema annulare centrifugum, proposed by Darier. The lesions arise as raised erythematous papules, firm to the touch but less so than those of granuloma annulare. They rapidly become transformed, by spreading peripherally while clearing in the centre, into rings or semi-circles, which attain a varying size and then fade, leaving slight pigmentation with, perhaps, some desquamation. Sometimes gyrate figures are produced by irregular extension or breaking-up of the original annular lesions. The sites of election are the trunk and proximal segments of the limbs. New elements continue to arise, sometimes after an interval at sites of pre-existing ones, but, as a rule, few are present at any one time, and there is little tendency to bilateral symmetry. The affection may last for months or years, with intervals of freedom.

Ætiology. The eruption, in the writer's opinion, may be regarded as a connecting-link between erythema multiforme and granuloma annulare. A comparison may, perhaps, be made with the syphilides, erythema multiforme corresponding to the widespread secondary lesions, erythema annulare centrifugum to the asymmetrical circinate syphilides of the late secondary stage, and granuloma annulare to the serpiginous tertiary lesions. It is probable that, as with erythema multiforme and granuloma annulare, erythema annulare centrifugum is not a specific entity, but a reaction of the skin to more than one toxin. The writer's own observations suggest that, as a rule, it is a streptococcide.

Diagnosis. It has to be distinguished from granuloma annulare, the elements of which are harder to the touch, less acutely erythematous, of much slower evolution, and more persistent: from annular syphilides, which never extend rapidly and are of longer duration: and from erysiploid.

Treatment. A history of previous acute illnesses, such as scarlet fever, tonsillitis, and puerperal fever, should be enquired for, and the presence of chronic foci of infection sought for and treated. The writer has found that intra-dermal injections of a streptococcal vaccine, prepared from various strains, are curative, at least in the majority of cases. The initial dose should be small—one to two million organisms—as severe local reactions often occur at the sites of injection; subsequent dosage depends upon the degree of reaction, and an increase should never be made as long as this is marked.

Granuloma Annulare. The elementary lesion of this rather rare eruption is a firm, pea-sized nodule, which is raised about $\frac{1}{8}$ th of an inch or somewhat more above the surface. By excentric extension, or by the appearance of new nodules, annular patches of varying size are produced. Their surface is smooth, their edges sharply defined, and the colour ranges from reddish-white to a dull purple. The central areas of the rings are usually stained a dark lilac colour, and may be studded with minute pale nodules, which remain discrete and may persist after resolution of the raised border. By irregular involution crescentic or festooned patches result. The eruption occurs most frequently on the backs of the hands, wrists, elbows, ankles, knees, buttocks, and neck. As a rule, the number of lesions is small, but in two cases observed by the writer they were numerous, and by wide extension involved large areas. The evolution is slow, and there may be little tendency to spontaneous resolution. Ulceration never occurs, and there is no subsequent scarring.

Ætiology. Although usually seen in children and adolescents, granuloma annulare may occur in middle and even late life. Its relationship to erythema multiforme and erythema annulare centrifugum has already been discussed, and in a patient, subject to recurrent attacks of the former, the writer has observed the gradual development of typical granuloma annulare from a patch of erythema multiforme. Moreover, in patients with lupus erythematosus there may occasionally be seen nodular and annular lesions, indistinguishable

clinically from granuloma annulare, which may coexist with or become transformed into those characteristics of this disease. It is clear that all these eruptions are closely related, and, although some consider that they are diseases *sui generis* and caused by infection with unknown specific organisms, it is probable that they represent a variety of non-specific reactions to different toxins. Granuloma annulare is considered to be, like lupus erythematosus, of tuberculous origin by many and this may be so in some cases, but in others it is more probably a streptococcide. Forman and the writer found in a series of eleven cases that 73 per cent. gave positive intradermal tests to *Streptococcus hæmolyticus*, 50 per cent. to *S. viridans*, and one case only (9 per cent.) reacted to tuberculin, the reaction being strongly positive. Moreover, in two widespread cases, observed by the writer, there was no evidence of tuberculosis. In one the eruption followed a severe streptococcal septicæmia after childbirth, and the other had suffered from chronic streptococcal infection for years. Both responded remarkably to intradermal injections of streptococcal vaccine, the reactions to which were initially severe, and this method of treatment has proved successful in other cases.

Morbid Anatomy. There is a central area of coagulation necrosis in the corium, surrounded by an infiltration of lymphocytes, epitheloid, and connective-tissue cells. Plasma and giant cells may be seen. The epidermis is intact.

Treatment. The local application of salicylic acid plaster may cause the lesions to disappear, and they yield to radiotherapy. The patient should be investigated for the presence of tuberculous or streptococcal infection, and treated accordingly. Darier advises tuberculin intradermally, and, as stated, the writer has found intradermal injections of streptococcal vaccine usually curative. It has been observed that a patch often disappears after excision of a small portion for microscopical examination.

ERYTHEMA NODOSUM

This consists of oval or circular solid flat elevations of the skin, from $\frac{1}{2}$ inch to $1\frac{1}{4}$ inch in diameter, bright or dusky red in colour, gradually shading off into the surrounding skin, tender to the touch, and perhaps pitting slightly on pressure. These occur most often over the whole length of both tibiæ, and not infrequently over both ulnæ. Though rare in other parts, they may be seen on the calf, on the thighs, over the scapulæ, and over the condyles of the humerus. They come out more or less in crops, last seven or ten days, and gradually subside with bruise-like staining. They may become soft and fluctuate, but never suppurate. They are most common in children and people under twenty years of age, and more frequent in girls than in boys. The appearance of the eruption is often preceded by a sore throat or tonsillitis, and is accompanied by some pyrexia, general malaise, pains in the joints, and sometimes by actual arthritis comparable to that of rheumatic fever.

Ætiology. Erythema nodosum may be regarded as the dermo-hypodermic counterpart of erythema multiforme, with which it may occasionally co-exist. There has been much discussion in recent years concerning its causation, and chiefly as regards its relationship to tuberculosis. Some consider that it may be due to infection with a specific micro-organism, for example, that which Rosenow claimed to have isolated from the nodes and blood in six patients with the disease, and Trousseau classed it among the exanthemata. There is general agreement that in some cases it may, like erythema multiforme, be a manifestation of streptococcal or rheumatic infection, and occasionally it is associated with endocarditis and pericarditis. Streptococci have been cultivated from the blood during an attack. Others have stressed its frequency in patients with gonorrhœa, and a syphilitic variety has been described. Certain drugs, *e.g.* iodides, antipyrine, may provoke a similar eruption.

Evidence has now, however, accumulated to suggest that in the majority of

instances it is of tuberculous origin. This view was maintained by Landouzy in 1907, and he later claimed (32) to have demonstrated a tubercle bacillus in a vessel of a nodule, and to have tuberculised a guinea-pig with another portion of the same nodule. Strongly positive Mantoux tests are obtained in a high proportion of cases. In a series of eighteen patients Forman and the writer (33) found that 54 per cent. gave a strongly positive and 38 per cent. a positive reaction to tuberculin—a total of 92 per cent. ; whereas in Erythema multiforme only 19 per cent. gave strongly positive and 23 per cent. positive reactions—a total of 42 per cent.

It would seem that Erythema nodosum is usually associated with a recent tuberculous infection, the primary site of inoculation being often small and immediately subpleural, and the hilar glands being rapidly and more extensively involved (34). It is probably from the latter that the invasion of the blood-stream by tubercle bacilli, on which the eruption depends, takes place. Not infrequently a history of recent contact with a person suffering from open tuberculosis is obtained. In other cases it may herald the reactivation of a latent tuberculous focus (*cp.* Erythema induratum), or may precede the adult form of pulmonary tuberculosis. Whitwell has recorded a case in which erythema nodosum followed a primary tuberculous infection of the skin with invasion of the neighbouring lymph-glands, tubercle bacilli being obtained from both sites. Subacute cases which form a transition between E. nodosum and E. induratum have been described.

Lastly, E. nodosum may be a rare form of trichophytide.

Bloch obtained focal reactions with injection of trichophytin, and Bruusgaard claims to have demonstrated spores in the nodules of his case, and to have cultivated the *Trichophyton gypseum* from the lesions, which was the fungus responsible for the original ringworm infection. To sum up, erythema nodosum is an allergic dermo-hypodermic reaction to emboli of circulating organisms, of which the tubercle bacillus would appear to be most frequently responsible.

Morbid Anatomy. In early lesions there is seen thrombosis of the subcutaneous arterioles and a dense infiltration with polymorphonuclear leucocytes of the surrounding subcutaneous fat. In later lesions, the polymorphonuclear leucocytes disappear and are replaced by lymphocytes. Giant-cells may be present during the process of repair, but are fat-phagocytes, and not indicative of a tuberculous lesion.

Prognosis. This must be guarded in cases in which a tuberculous infection is apparently responsible for the eruption. Several instances have been recorded in which manifestations of active tuberculosis have supervened within six months of an attack of erythema nodosum, and in some death from miliary tuberculosis has occurred. The outlook is graver in children and adolescents, since in them a tuberculous origin is more likely, whereas it would appear that in adults infection of the throat with a hæmolytic streptococcus is often responsible.

Treatment. The patient should remain in bed pending the results of investigations, which should include a clinical and radiographic examination of the chest, tuberculin tests, and, in cases suspected to be of streptococcal origin, an estimation of the anti-streptolysin in the blood. Careful inquiry should be made for previous contact with a person suffering from open tuberculosis. Such contact explains the epidemics of Erythema nodosum that sometimes occur in families and schools. Forman observed a family of eight children, five of whom developed the eruption after being in contact with an older member of the family with active phthisis. If investigation reveals evidence of tuberculosis, the case should be notified, and the usual methods employed to combat this disease should be instituted at once. In any case, the patient should be kept under close observation for several months. If infection with a hæmolytic streptococcus appears to be causal, chronic foci, such as the tonsils, should be dealt with, and, should recurrent attacks occur, intradermal injections of an

autogenous or stock streptococcal vaccine should be given, as advised for recurrent Erythema multiforme. In all cases, a vitamin-rich dietary and calcium salts should be prescribed, and the patient should live out of doors as much as possible.

ERYTHEMA PERNIO

(*Chilblain.*)

Chilblains consist of bluish-red tumefactions of the skin, which occur in certain persons on exposure to cold or during a sudden drop in atmospheric temperature. They are seen most commonly on the fingers and toes and on other parts of the hands and feet, but the ears, tip of the nose, cheeks, and, in young girls with erythrocyanosis, the lower parts of the legs may be affected. They may be circumscribed or diffuse. They give rise to sensations of itching, tingling, or actual pain. As a rule they gradually subside, but sometimes the serous exudation in the corium is sufficient to raise the epidermis so as to form a thick-walled vesicle, which ruptures, leaving an indolent ulceration ("open chilblain"); this may become secondarily infected with pyogenic bacteria. Healing takes place slowly with or without scar-formation. In other cases there is no ulceration, but the overlying horny layer becomes thickened and then splits, causing painful fissures. Severe ulcerated chilblains may sometimes completely incapacitate the patient from manual work or even from walking.

Ætiology. Although usually seen in children and adolescents, chilblains may occur in middle and late life. They naturally form more readily in those with a poor peripheral circulation ("chilblain circulation") and a tendency to "dead fingers," dependent upon spasmodic contraction of the arteries, or to acrocyanosis. But some persons of this type never develop chilblains, and conversely the latter may occur in those without this tendency. Cold, particularly damp cold, is the immediate provoking factor, and a sojourn in a damp place or house may cause the appearance of chilblains in a person previously immune. Malnutrition, anæmia, and arterial hypotension are predisposing factors, and many victims are tubercular subjects.

It is clear that underaction of the accelerator group of endocrine glands—thyroid, pituitary, and ovaries—is probably of ætiological significance; a deficiency of the circulating pituitary hormone, which is the chief regulator of capillary tone and appears to decrease the permeability of the walls of the minute vessels, may well be the most important single factor in the genesis of acrocyanosis and chilblains.

Pathology. Normally, exposure of the skin to cold causes contraction of the small vessels and capillaries with consequent pallor; this is followed by a reaction in the form of an erythema, due to vaso-dilatation, which gradually subsides. If, however, the vasomotor tone is deficient, the vessels and capillaries remain distended, and serum, or even blood, escapes from the tissues, the permeability of the walls being increased. Chilblains may therefore be said to result from static erythema with œdema.

Diagnosis. Chilblains have to be distinguished from papulo-necrotic tuberculides, lupus erythematosus, and, when they occur on the legs of girls with erythrocyanosis, from erythema induratum, with all of which conditions they are likely to co-exist, since these are met with in persons with a chilblain circulation.

Treatment. The state of the patient's general health and the mode of life must be considered. A generous dietary with plenty of milk, eggs, and butter, if well tolerated, should be prescribed, and this should be supplemented in winter with cod-liver oil or one of the proprietary vitamin-concentrates. The administration of small doses of thyroid is of undoubted value; this may be combined with large doses of whole pituitary gland, but it is preferable to give intramuscular

injections of pituitrin. In females with irregular or scanty menstruation active ovarian extracts are indicated. Calcium salts appear almost specific in some cases, but are disappointing in others; calcium lactate in doses of 15 to 30 grains thrice daily, the syr. calcii lactophosphat. B.P., or one of the proprietary preparations should always be tried. Vigorous outdoor exercise and simple gymnastics should be enjoined, and warm gloves and stockings must be worn. A course of local and general applications of ultra-violet light is often of striking benefit. Locally, galvanic baths improve the circulation very effectively, and should be given for ten minutes daily. Very good results are also obtained by immersing the affected parts in a mixture of hydrogen peroxide (15 to 20 vols.) and hot water for a quarter of an hour every night, followed by the application of a stimulating preparation, such as iodex or a methyl-salicylate ointment.

Livedo (*Cutis marmorata*). This is another example of the effect of circulatory stasis in the skin. It is seen chiefly on the extensor surfaces of the legs, thighs, and upper arms, and sometimes on the flanks. It consists of a bluish network, with reticulations of considerable size enclosing areas of normal colour. It is made more apparent by exposure to cold. It appears to depend upon the distribution of the main arteriolar territories, the central pale areas receiving a direct supply from the underlying arterioles, and the reticulations corresponding to sites of anastomosis, where the blood flow is naturally more sluggish. The tone of the vessels in the reticulations is also diminished, and they are relatively irresponsive to adrenalin and histamine. The eruptions of measles and secondary syphilis occur first in these reticulations, and the same is true of those due to copaiba and salvarsan, and sometimes of lichen planus and parapsoriasis.

Erythema Ab Igne (*Ephelis ab igne. Cutis marmorata pigmentosa*).—This condition results from frequent exposure of the skin to heat, and is most commonly seen on the fronts of the legs in those who are constantly sitting in front of a fire, and in stokers and cooks. It may also occur on the abdomen or elsewhere from repeated use of hot-water bottles. The discoloration corresponds to the reticulations of livedo, and varies in tint from light brown to a deep reddish-purple; it is partly caused by dilatation of the superficial vessels in the marginal areas, where, as already noted, the circulation is normally more sluggish and the tone of the vessels diminished, and partly by a heavy deposit of melanin in the basal layer of the overlying epidermis. Microscopically there is seen an inflammatory cell-infiltration of the corium around the blood-vessels. Occasionally, the markings are distinctly raised, due, perhaps, to thickening of the vessel walls (Perry).

Erythrocyanosis Crurum Puellaris. This condition, which of recent years, owing to the advent of short skirts and thin stockings, has become very familiar, is a variety of acrocyanosis met with in girls and young women. It is seen on the lowest third of the leg, chiefly on the postero-external surface. The affected part is swollen, cold to the touch, and bluish-red or dark-lilac in colour. On the surface may be seen a pattern of dilated venules. As a rule the patients are fat and phlegmatic, with large bones, thick ankles, and a chilblain circulation. Very often a history is obtained that they grew rapidly and became abnormally fat and big at puberty, probably owing to over-activity of the anterior part of the pituitary gland at that time. The legs as a whole are large and unshapely from excess of subcutaneous fat, and a characteristic feature is the presence of keratosis pilaris and of a bluish halo around each follicle. The patients may complain of aching in the legs, and in winter painful chilblains of large size may form at the site of maximum circulatory stasis. These may be mistaken for the nodules of erythema induratum, since it is in girls of this type with erythrocyanosis of the legs that this eruption is likely to occur should an active tuberculous focus exist. The nodules, however, are firmer to the touch, deeper and more sharply circumscribed than chilblains.

Ætiology. The condition is seen almost exclusively in young girls and women of the type already described, but may occur occasionally in thin subjects. It would appear certain that an endocrine dyscrasia, which may be inherited, is the primary factor. As with chilblains, a deficiency of the posterior pituitary hormone is, perhaps, of chief importance, but thyroid and ovarian insufficiency may also play a part. Amenorrhœa or irregular and scanty menstruation are often present, but not constantly. Exposure of the legs to cold is, of course, the chief contributory factor.

Treatment. The general indications are those already given for chilblains. Warm woollen stockings and anklets should be worn, and, although vigorous exercise is beneficial, the patient should avoid standing for long periods.

LUPUS ERYTHEMATOSUS (See Plate 60)

This disease occurs mostly in adults, especially between the ages of twenty and forty, is very rare in children, and is more common in women than in men. Its early recognition is of great importance, since it affects chiefly the face, and, as the lesions often result in scarring, it may cause permanent disfigurement. Various forms of the eruption are recognised, although they may all coexist in the same patient. In the majority of cases the disease begins as a red, injected, desquamating patch, with a well-defined, irregular, and slightly raised edge. If a piece of scale be removed, there will often be seen little horny plugs projecting from the under-surface; these fit into depressions in the epidermis, which, after removal of the scale, are recognised as small pits on the denuded surface of the patch. Dilated venules are usually visible, and in one variety the formation of telangiectases is very marked. As the disease spreads peripherally, involution often occurs in the centre, so that after a while there is a central, depressed, pale scar surrounded by a raised, red, scaly edge. The scar formation is not preceded by ulceration. These cases are usually, but not always, tuberculous in origin. In another variety, which is commonly due to streptococcal infection, there is no scale formation, but the disease appears as raised, œdematous patches of erythema, closely resembling, and, indeed, often indistinguishable from, those seen in *Erythema multiforme*. In this erythematous type scarring is very slight, and may be entirely absent, the patches of erythema eventually disappearing without leaving any trace. Although the eruption is usually of limited extent, it may occur in an acute generalised form from the onset, or, more commonly, after a few chronic patches have been present for some time. In the acute form the recent patches either resemble those of *Erythema multiforme*, or they may be mistaken for eczema, although actual vesiculation is rarely seen.

Distribution. This is important from the diagnostic standpoint. The commonest sites are the malar eminences, the nose, the ears, the scalp, the backs of the hands and fingers, and the vermilion border of the lips. The distribution tends to be symmetrical, and often patches occur on either cheek and across the nose, so that the outline of a butterfly or bat is simulated—a very characteristic feature. The disease may rarely begin on the scalp or on the fingers before the face is involved. On the scalp atrophy of the hair follicles occurs, and patches of permanent alopecia, usually traversed by telangiectases, result. The ears are affected along the edges, which become eroded, irregular in outline, and shrunken, and the inner surface of the auricle is also involved. The mucous membranes of the mouth, nose and conjunctiva may be attacked, but, except for the lips, they are usually spared.

The subjective symptoms may be slight, but there is often great irritation in the patches, and many patients complain of intense burning, particularly after meals, or on exposure to sun or wind. The disease is not infrequently associated with rheumatoid arthritis of varying severity. In the acute generalised form there is pyrexia, sometimes of the septicæmic type, and there may be albuminuria; these cases may terminate fatally.

Ætiology. As will be evident from the above description, the eruption tends to involve those situations in which circulatory stasis is apt to occur, namely the fingers and toes, the backs of the hands, the ears, and the rosaceous or "butterfly" area of the face, and in people with marked acroasphyxia the hands, feet, and ears may be the chief or only parts affected, whereas in those with a pre-existing rosacea the "butterfly" area is likely to be the site of predilection. Frequently, however, rosacea and a "chilblain-circulation" coexist, in which case all the above sites may be involved in the same patient. Since the eruption is produced by circulating toxins—perhaps, even, by an actual bacteriæmia—and is essentially chronic, it is obvious that the inflammatory reaction, which constitutes the lesions, is most likely to appear where there is vascular stasis; moreover, certain areas of skin evidently become sensitised to the toxins, so that recurrence may take place in the identical situations previously involved, when there is a recrudescence of the toxæmia after temporary disappearance of the eruption. As to the nature of the toxins or micro-organisms causing the disease, there are now two predominant views; one, which obtains most favour on the Continent, is that it is a tuberculide, the other that it is a manifestation of chronic or acute streptococcal infection. Many now incline to the opinion that, like other forms of erythema, it is not a specific entity, but that both tuberculous and streptococcal infection (and possibly others) may be responsible in different cases.

In favour of its tuberculous origin in some cases, its occurrence in those with a strong family history of tuberculosis, its association with manifest tuberculous infection of glands, bones, joints, lungs, etc., and the claims that guinea-pigs have been tuberculised by inoculation of the affected tissue may be mentioned (35). On the other hand, no trace whatever of tuberculosis has been found in some fatal cases of the disease. Convincing evidence has been produced that in some cases acute or chronic streptococcal infection is the cause (36). The primary sources may be the teeth, nasal sinuses, tonsils, and probably the prostate and female genital organs; in many cases there is a secondary and persistent intestinal infection with a *Streptococcus longus*, which may rarely be recovered from the fæces in almost pure culture. In fatal cases a *Streptococcus longus* has been obtained from the blood during life. Certainly the fatal cases reported have resembled clinically streptococcal septicæmia rather than general tuberculosis. It must be remembered that, as in chronic tuberculosis, cases of chronic streptococcal infection have as a rule both primary and secondary foci, and the removal of obvious and accessible sources of infection does not necessarily suffice to cure, owing to the existence of subsidiary foci in lymphatic glands, the intestines and elsewhere.

Diagnosis. The conditions which are most likely to be mistaken for *Lupus erythematosus* are rosacea, *Erythema multiforme* and *Erythema pernio*, eczema, psoriasis, and *Lupus vulgaris*. The distribution, the persistence, the resistance to local treatment, and the tendency to superficial scarring, are the chief characteristics on which the diagnosis rests. From *Lupus vulgaris* the main points of distinction are that *Lupus erythematosus* very rarely begins in childhood, it is usually bilaterally symmetrical, it never ulcerates, and never destroys cartilage, it frequently involves the scalp, the scarring from it is superficial, it only rarely reacts to injections of tuberculin, and the characteristic apple-jelly nodules are absent.

Morbid Anatomy. In the *dermis* is seen a diffuse, but chiefly perivascular infiltration with lymphocytes and small connective-tissue cells, and occasional plasma cells and polymorphonuclear leucocytes. Giant-cells of the phagocytic type have been observed near disintegrated follicles. There is oedema of the papillæ and dilatation of the lymphatics. Some of the blood vessels are dilated, others obliterated, and small hæmorrhages may be seen. In the *epidermis* the rete malpighii is atrophied, and may be reduced to only a few rows of cells, the stratum granulosum being absent at certain points. The stratum corneum is, on the other hand, thickened, and horny plugs fill the openings of the follicles and

sweat-ducts. The atrophy is due to the disappearance of the connective-tissue and elastic fibres. The hairs fall, and the glands, at first dilated, are ultimately destroyed.

Treatment. The treatment of this chronic and disfiguring disease has been rendered far more satisfactory in recent years, since the introduction of gold compounds, such as Sanocrysin, Krysolgan, Solganal, and similar preparations. In the majority of cases the results are good, but in some they are disappointing. It would seem that those cases in which the eruption appears to be of tuberculous origin respond more readily than those apparently due to streptococcal infection. The dosage of these gold compounds depends upon the preparation employed, and the tolerance of the individual patient. Occasionally toxic symptoms—fever, general malaise, pruritus, and a generalised erythematous or lichenoid rash, with involvement of the buccal mucous membrane—may arise, as in other forms of metallic intoxication; the occurrence of such symptoms probably depends upon a failure of hepatic function, and they are more liable to occur in alcoholics, or others with manifest hepatic insufficiency. The administration of glucose, 2 to 3 ounces *per diem* in divided doses, for two or three days before each injection, appears to have a prophylactic effect, and full doses of calcium gluconate are also recommended. In some cases injections of bismuth preparations appear more effective than those of gold salts, and recently intravenous or intramuscular injections of antileprol have been employed with success.—

Internally iodine in increasing doses appears to do more good than any other drug that has yet been tried. It should be given as a 10 per cent. solution in rectified spirit, and should *not* be combined with iodide of potassium. Of this solution 5 drops daily in milk should be taken at first, the dose being increased gradually up to 40 drops in divided doses *per diem* if well tolerated. Very much larger doses have been given without ill effect, but instances of intolerance are met with. Cod-liver oil is often of great benefit, but is apt to upset the digestion. Instead, one of the proprietary vitamin concentrates may be taken, and the patient should be given plenty of milk and other foods rich in calcium.—Quinine and salicin appear sometimes to be of value, especially in the more acute cases. When the eruption appears to depend on chronic streptococcal infection, accessible infective foci should be sought for and dealt with, and the subsequent administration of an autogenous streptococcal vaccine over a long period in suitable dosage would appear of definite value. In severe cases prolonged rest in bed, preferably out of doors, should be insisted upon. Judicious heliotherapy or artificial light baths are in some cases of striking benefit, but it is advisable at first to protect the actual eruption from the rays, which may, until tolerance is established, aggravate it and cause it to become acute.

Locally. In the acute and hyperæmic cases cooling lotions such as those of calamine and lead should be applied. In more chronic cases, without much infiltration, continuous compression with non-flexible collodion, to which 2 per cent. of salicylic acid may be added, sometimes results in improvement and even disappearance of the patches. Chronic patches of the fixed type may be treated more energetically. The scales should be removed with soft soap and spirit, or a salicylic acid plaster, and the patches may then be painted with tincture of iodine, while quinine is simultaneously administered internally (Hollander). Or the patches may be rubbed once a week with a glass rod dipped in a mixture of lactic acid 4 parts, carbolic acid 1 part. Repeated applications of solid carbon dioxide snow for fifteen seconds with moderate pressure, though causing a severe reaction, may bring about the disappearance of chronic patches. Ionisation with zinc or copper sulphate, scarification, and even cauterisation, have been used with varying results. The X-rays and the Finsen light are more likely to do harm than good. It should be remembered that local treatment, though of great value, does not prevent recurrences, and for this reason every effort should be made to locate the underlying infection responsible for the disease.

ROSACEA

(Acne Rosacea—Gutta Rosea)

In the earliest stage of the disease there is periodical flushing of the face, occurring usually after meals or on exposure to heat and cold. At first the hyperæmia affects the nose and malar regions, but later it extends to the centre of the forehead and the chin. After a while the flushing tends to become permanent, although it varies in intensity at different times, and eventually telangiectases appear; they are particularly numerous in persons with a feeble peripheral circulation. In most cases the flushing is accompanied by seborrhœa, and sometimes by hyperidrosis, and secondary inflammation is very apt to occur around the pilo-sebaceous follicles, resulting in the formation of pustules and papules, which cause great disfigurement. Fresh outbreaks of these inflammatory lesions occur periodically, and in women they are apt to be most numerous just before the menstrual periods; an indigestible meal or indulgence in alcoholic liquor may invariably provoke an outbreak in certain cases. Although the disease is usually most evident on the nose and cheeks, it may affect chiefly the chin, particularly in women; in such patients, crops of indolent, red papules and pustules continually appear in this situation. This variety is said to be associated with ovarian or uterine disorders. In another variety of the disease the skin, instead of being greasy, is dry, and superficial, red, scaly patches, intermingled with small pustules, appear on the hyperæmic areas. In some cases of cirrhosis of the liver intense rosacea, with severe secondary staphylococcal infection, may involve not only the "flush-area," but also the posterior parts of the cheeks and forehead, and even the ears and submaxillary regions. Two examples of this kind have been seen by the writer in young girls with cirrhosis.

In long-standing cases of rosacea the condition known as rhinophyma may arise. It is seen most commonly in men of alcoholic habits, whose employment exposes them to cold winds. The nose becomes covered with large, lobulated or pendulous protuberances, separated by deep furrows; their colour is deep violet, and their surfaces traversed by large dilated veins, and pitted by the dilated follicles of the hypertrophied sebaceous glands.

The dyspeptic symptoms of patients with rosacea sometimes depend on chronic gastritis with hypochlorhydria. There is a feeling of fullness after meals, flatulence, and sometimes heart-burn and a sensation of nausea. The appetite is often poor, and the bowels constipated. On the other hand, subjective symptoms of dyspepsia may be absent.

An important complication of rosacea is the occurrence of ocular lesions, which are met with in about 15 per cent. of cases. Chronic blepharitis, however, which is so common in seborrhœic subjects, is seen with greater frequency. The ocular lesions may be classified as follows:—

- (1) Simple dilatation of the conjunctival vessels, the conjunctivæ being included in the rosaceous area of the face;
- (2) phlyctenular conjunctivitis;
- (3) corneal ulceration, resulting from the breaking-down of phlyctenules;
- (4) diffuse keratosis.

The last three are evidently the result of a pyogenic infection, comparable to that which occurs on the skin of the rosaceous area, but there is not necessarily any parallel as regards the intensity of the two, and occasionally the eye-lesions may precede the active manifestations of rosacea. Although successful treatment of the latter usually leads to a cessation of the ocular inflammation, the corneal ulceration may be severe and intractable, and the resulting scars cause permanent impairment of vision.

Anatomy. In the early stages there is merely dilatation of the capillaries in the corium, particularly around the pilo-sebaceous follicles and the sweat-glands, with some small-celled infiltration. The papules are formed by chronic inflam-

mation around the follicles. In rhinophyma there is enormous hypertrophy of the sebaceous glands, with new formation of fibrous tissue.

Ætiology. Rosacea may occur in adolescence, but usually begins in the third or fourth decade, diminishing or disappearing in later years. It is far commoner in women than in men, and the menstrual periods and the menopause undoubtedly aggravate the tendency when it exists. Two types of the disorder may be recognised, according to whether the hyperæmia is active or passive. In the former case the affected area is bright red, and the flushing is intensified by indigestion, hot drinks, exposure to heat, or emotional disturbance; in the latter there is passive congestion, so that the colour is bluish or purple, and exposure to cold is the chief aggravating factor. The passive form is also met with in those with chronic cardiac or pulmonary disease. In both forms, however, circulatory disturbances are common, in that the peripheral vasomotor tone is unstable. The extremities are often cold, or alternately hot and cold, and many patients, particularly women, are subject to "dead fingers," such as are seen in Raynaud's disease. In the passive form a "chilblain circulation" is the rule, and the rosacea may be merely part of this, there being stasis in the superficial vessels of the nose and malar regions on exposure to cold. Ætiologically this is distinct from true rosacea, although the two may co-exist.

Recent observations (37) suggest that in the latter the usual immediate cause of the reflex flushing of the rosaceous area is an increase of tension in the stomach wall, which may be due to (a) delay in emptying, (b) feeble peristalsis, (c) hypotonia, which renders the stomach liable to distension, (d) over-rapid peristalsis, and (e) gastric spasm. Consequently anything which produces gastric distension, such as bulky, insufficiently-masticated meals, white bread, and a large quantity of fluid, or which interferes with normal peristalsis, will provoke the flushing. Contributory factors, of which there are many, e.g. menstruation, the menopause, painful disorders of the female pelvic organs, chronic infections, and psychological disturbances, such as the anxiety state, probably owe their effect to their action on the gastric tone. It has been shown (38) that prolonged anxiety causes hypotonicity of the stomach and inhibition of peristalsis, and that a similar condition occurs in women during the premenstruum. It is uncertain to what extent a definite gastritis is present. Numerous observations upon the results of fractional test meals in patients with rosacea have been made and it has been established that there is no correlation between the gastric acidity and the rosaceous tendency, since the secretion of hydrochloric acid may be absent, deficient, normal or excessive. Although the administration of hydrochloric acid is often of striking benefit, it may be equally so in cases with hypochlorhydria and with a normal or even excessive secretion of acid. Its action, therefore, probably depends upon its influence on the gastric tone and peristalsis. Alkalies, given before meals, and carminatives doubtless act in the same way. The frequency of rosacea in chronic alcoholics and tea-drinkers may be partly due to gastritis, partly to hypotonia and distension from large quantities of fluid, and partly to aggravation of the flushing by alcohol and hot fluids.

Diagnosis. Rosacea may be distinguished from *Acne vulgaris* by the absence of comedones, and by the fact that it appears later in life. The two conditions, however, frequently coexist. In *Lupus erythematosus* there are usually well-defined patches, with raised borders and adherent scales, and superficial scarring is apt to result. The diagnosis from the rosaceous tuberculide has already been discussed. Confusion with syphilitic eruptions should not arise.

✓ **Treatment.** The patient must avoid heavy meals, the taking of large quantities of fluid, and eating when tired. White bread should be taboo, for it has been demonstrated in a patient with a jejunal fistula that, whereas when crisp toast was eaten only a small amount of liquid material appeared at the fistula, if white bread was taken large doughy lumps were passed. Other soft starchy foods should also be avoided, such as milk- and suet-puddings, heavy

cakes, and porridge. Alcohol should be taken very sparingly or not at all, and strong tea or coffee and other hot drinks must be forbidden. Oral, tonsillar, or naso-pharyngeal sepsis must be most carefully sought for, and dealt with if present. Examination of the gastric juice by the fractional method is always desirable, and in some cases an X-ray examination of the whole alimentary tract is indicated. In most cases the best results are obtained by giving an alkaline mixture before meals, *e.g.* R. Sod. Bicarb. gr. xx., Tinct. Rhei Co. ℥xl., Tinct. Zingiberis ℥xxx., Aq. chlorof. ad ℥i: and full doses of dilute hydrochloric acid (30 to 40 minims), either during or after the three principal meals of the day. Other drugs that are sometimes of value are bismuth and ichthyol; both should be given on an empty stomach. The possible influence of emotional stress and an uncongenial environment must always be considered, and judicious psychotherapy is sometimes of striking benefit. In women with menstrual irregularities, and during the menopause, active ovarian extracts are indicated. Locally, the main indication is to check seborrhœa and the resulting secondary infection. In mild cases a weak ichthyol cream or paste may be applied at night-time and calamine lotion during the day. In more severe cases a paste containing sulphur, salicylic acid, and resorcin may be applied at night. Lassar's paste, containing 2 per cent. of yellow oxide of mercury, is of value if there is much pustulation. Dilated venules may be destroyed by electrolysis or by repeated light freezing with carbon-dioxide snow. In rhinophyma excellent cosmetic results may be obtained by removal of the hypertrophied tissue with the knife. Small doses of X-rays are sometimes of value.

URTICARIA

The essential lesions of the eruption of "nettlerash" (*Urtica*, a nettle) are wheals (*pomphi*, hives). These are firm, convex elevations of the skin, pink in colour, or with a white centre, where the œdema is most intense, surrounded by a red areola or "flare"; they may be round, oval or linear, and sometimes form gyrate figures. In size they vary from small, sharply-defined papules (*U. papulata*) to large plaques of wide extent. Rarely a vesicle or bulla may form on the surface of the wheal (*U. bullosa*). In giant urticaria (*U. gigans*) the serous exudation is subcutaneous (angeioneurotic œdema), and more or less circumscribed nodules of the size of a hen's egg, or larger, occur, or there may be diffuse swelling of parts such as the eyelids, lips and extremities. Both in ordinary urticaria and the giant form the individual lesions are ephemeral, lasting from a few minutes to some hours. The eruption is accompanied by intense itching, so that the patient cannot forbear from scratching himself, thereby often causing new wheals to arise (*U. factitia*).

A distinction must be drawn between this factitious urticaria and dermographism. The former, as has been said, is produced by scratching or rubbing the skin of a person in an urticarial state. On the other hand, certain people, who are not urticarial, develop similar wheals, even on gentle stroking of their skin. This phenomenon is known as *dermographism*, and it differs from true urticaria in that there is no accompanying itching. The tendency to dermographism, however, is a matter of degree, and a considerable proportion of normal subjects show some whealing as a sequel to firm stroking.

Ætiology. The wheal, however produced, is a complex reaction, named by Lewis (39) the "triple response." It comprises (a) a primary and local dilatation of the minute vessels of the skin, (b) a widespread dilatation of the neighbouring arterioles, resulting in the "flare," and brought about entirely through a local nervous reflex, and (c) locally, increased permeability of the vessel walls, with exudation of serous fluid rich in albumin. Occasionally there is round-celled infiltration round the dilated vessels. This complex reaction can be evoked by stimuli of very different kinds, namely mechanical, thermal, electrical,

and chemical, but it is probable that, *whatever the exciting cause*, the wheal is due to the liberation of histamine or a histamine-like substance in the skin. Typical wheals can, of course, be experimentally produced by injecting a solution (e.g. 1 in 3,000) of histamine into the skin.

The urticarial or dermographic wheal may be regarded as a purposive local reaction to injury ; by means of the "triple response," upon which its formation depends, there is an increased blood-flow and lymph-supply to the injured area, which "will tend to wash away or dilute injurious substances, and will bring leucocytes more quickly through the vessels of the affected region" (Lewis).

The urticarial wheal is one of the commonest cutaneous reactions towards irritant substances, either when applied locally to the skin or when absorbed from within, and to injury by physical stimuli. Apart from histamine, a large number of chemical substances—acids, alkalies, formaldehyde, the salts of certain metals and alkaloids, iodine, mustard oil, cantharidin, etc.—will produce wheals if injected into the skin. Here, as a rule, the question of sensitisation, to be referred to later, does not arise, and the same is true for nettle-stings, and to some extent for those of stinging-insects. On the other hand, in the case of bites from insects, such as fleas, mosquitoes, gnats and lice, the factors of sensitisation and immunity must be considered. Persons bitten for the first time by rat-fleas show no reaction, but, after repeated bites, marked local reactions occur, the persons having become sensitised (40). Immunity may develop in those who are repeatedly bitten by certain insects over a long period. Thus natives, in areas where *Simulium* flies are plentiful, become immune to their bites (41), and it is well known that those who are constantly exposed to the bites of fleas, lice and bugs, in time show little or no reaction.

With regard to urticaria of internal origin, it must be remembered that, apart from a purely urticarial eruption, with or without its subcutaneous variety, urticarial wheals may occur in various conditions of toxic origin, such as dermatitis herpetiformis, the different forms of prurigo, and in light sensitisation. In many instances, for example, drug-, food- or serum-rashes, the eruption is polymorphic, there being erythematous patches of varying hue and configuration, mingled with urticarial wheals, and sometimes eczematous. A mixed urticarial and eczematous eruption very commonly follows the ingestion of certain foods, particularly fish.

Urticaria and aneurotic oedema are essentially neuro-vascular reactions, dermic in the former, hypodermic in the latter : the *epidermis* remains intact, except that in the rare bullous urticaria it is raised entire or infiltrated by the intense serous exudation. In eczema, on the other hand, as will be seen, the essential factor is *epidermal* sensitisation, and an eczematous reaction of the skin is an epidermo-dermal one. It is easy to understand how a mixed urticarial and eczematous eruption can be provoked by the same antigen, if both the dermal and epidermal tissues are sensitised to it.

Urticaria of internal origin is presumably always an indication that the person is in a sensitised or allergic state ; in some cases the eruption is provoked suddenly and for the first time after a hot bath or violent exercise, whereby no doubt there occurs a flooding of the cutaneous vessels with the circulating antigen, and in certain chronic cases the attacks only take place when congestion of the skin is produced by a physical stimulus, or under the stress of some emotion. The actual eruption is doubtless due to the liberation of histamine by the contact of circulating antigen with the sensitised dermal tissue, *i.e.* in response to injury. In a person sensitive to a given substance, e.g. fish or egg, the injection of a diluted extract of the antigenic substance and of a solution of histamine into the skin give exactly similar reactions simultaneously. Moreover, the histamine renders the area of skin to which it has been applied refractory to the antigenic solution, and the latter renders its area refractory to histamine.

The number of substances capable of causing an urticarial eruption of internal origin is enormous ; they may be classified as follows :

(1) *Food and Drinks.* As common examples may be mentioned fish, crustacea, bivalves, pork and sausage, eggs, mushrooms, nuts, cereals, certain fruits and vegetables, wines and other beverages. The antigens in these substances are not themselves proteins, since they are contained in a protein-free dialysate of the substance in question, as has been shown, for example, with egg (42). In some cases sensitiveness to a certain food is so great that merely taking it into the mouth may provoke an attack. In others an outbreak may depend upon incomplete digestion with consequent absorption of the antigen unchanged ; in patients with achlorhydria the administration of hydrochloric acid may prevent an attack even when a food which usually causes urticaria is taken. Some patients are sensitive to one food only, others to several, and in others again, although it is clear that the antigen is absorbed from the alimentary tract, no particular foods can be incriminated.

(2) *Drugs.* Numerous medicinal substances may provoke urticarial or erythematous-urticarial rashes, *e.g.* the balsams, opium, quinine, salicylates, iodides, the barbitone group of hypnotics, arsenic, arsenobenzol, and many others.

(3) *Therapeutic Sera.* Serum sickness, of which urticaria is a prominent symptom, is due to the horse-serum, not to the contained antitoxin, hence the danger of serotherapy in those already horse-sensitive.

(4) *Bacterial Infections.* Chronic urticaria may be dependent upon some focal infection, *e.g.* infected teeth, tonsils, or nasal sinuses, chronic appendicitis, cholecystitis or prostatitis, to *B. coli* infection of the urinary tract, and to the presence of abnormal coliform bacteria in the intestine.

(5) *Animal Parasites.*—Intestinal worms, hydatids, and parasitic protozoa. W. Jadassohn has shown that the actual antigen of the ascaris worm, which provokes violent urticaria, asthma, or eczema in sensitised persons, is not destroyed by heat and is dialysable ; as in the case of food antigens, therefore, it is not a protein.

Both when the antigen is absorbed from the alimentary canal, and in some cases, at any rate, when it is of parenteral origin, the proteopexic and detoxicating functions of the liver probably play a predominant rôle in preventing allergic reactions, such as urticaria. The liver, in fact, may be regarded as the first line of defence, and when this fails, the skin, owing to its ability to form antibodies and to fix those circulating in the blood (as evidenced by the Prausnitz-Küstner reaction), may take on a vicarious protective function. Urticaria and other cutaneous manifestations of allergy may be regarded as antigen-antibody reactions designed to destroy the former, thereby protecting other more vital organs. In serum sickness, in certain prurigos, in some cases of acute urticaria and angioneurotic oedema, and in urticarial and other eruptions secondary to metallic intoxication (arsenobenzol, bismuth, gold, &c.), a positive Van den Bergh reaction of the biphasic type is often found, with excess of urobilin in the urine, deposition of urates, and other indications of hepatic insufficiency. It has been shown that glycogen is essential for the antitoxic and other functions of the liver, and this may partly explain the value of glucose in preventing metallic intoxication, and in the treatment of certain allergic conditions.

During an acute attack of urticaria the various phenomena included under the term " hæmoclastic crisis " occur, and the same biochemical changes in the blood and urine that characterise other manifestations of the allergic state (*see p. 138*). There is retention of fluid, the wheals representing local accumulations in the dermis.

Apart from the essential factor of sensitisation, there may in certain cases be others predisposing to urticaria, such as calcium deficiency and psychological disturbances. Certainly some cases are benefited by the administration of calcium

salts, and in an urticarial subject an attack may be provoked by an emotional upset (cp. asthma, prurigo).

Treatment. An acute attack of urticaria, occurring for the first time, usually follows the ingestion of some food, such as fish, shell-fish or pork, the antigenic substance not having been destroyed by digestion, and having escaped fixation and destruction by the liver; the possibility of it being due to some drug, *e.g.* a hypnotic, or to the injection of a therapeutic serum must, however, be considered. If the patient is seen shortly after a suspected food has been taken, an emetic may be given, and for the immediate relief of symptoms Liq. adrenalini hydrochlor. 5 to 10 minims, or, better, a compound of adrenalin and pituitrin, should be injected deeply in the subcutaneous tissue, and repeated at intervals if necessary. Intravenous injections of calcium compounds, *e.g.* calcium gluconate or *afenil* (calcium chloride-urea), are also effective and may be given daily for a while. It is advisable that the patient should remain without food for twenty-four hours, except that he may be given glucose dissolved in hot water. Unless there is intolerance of milk, the diet should then be restricted to four tumblers per diem of this fluid, sweetened with glucose, for two or three days. A purge, such as calomel gr. 2-3, followed by a dose of the aperient sulphates in hot water the next morning, should be given at the outset of this treatment.

In cases with chronic urticaria or recurrent attacks an attempt should be made, by closely questioning the patient or, if necessary, by performing cutaneous tests, to incriminate certain foods, and a thorough search should be instituted for sources of focal infection. It may be advisable to investigate the gastric secretion of hydrochloric acid by a fractional test meal, and the fæces for abnormal strains of bacteria, evidence of excessive putrefaction, undigested food, and intestinal parasites. A total and differential leucocyte count may indicate latent sepsis, or, if there be eosinophilia, hydatid disease. A complete examination of the urine, specimens being collected at different times throughout a period of twenty-four hours, may reveal the cycle of changes already described in allergic conditions, and give a clue to rational treatment. Coliuria should be treated with hexamine or other urinary antiseptics.

✓ **Diet.** The dietetic treatment of chronic urticaria naturally demands the exclusion of foods which appear to provoke the attacks, and very acid fruits, fatty foods, except butter and plain cheeses, recooked meat and fish, crustacea and shell-fish, and concentrated sweetstuffs should be avoided. Some cases appear to benefit from temporary vegetarianism, but in the majority a dietary rich in protein, with restriction of carbohydrate and fat and a plentiful supply of vegetables and of the less acid fruits, is advisable. The fluid intake should be limited to two pints *per diem* exclusive of that obtained from fruit and vegetables, salt should be taken very sparingly, and glucose should be substituted for cane-sugar. The following may be cited as an example of such a dietary, which may be modified according to the tastes and idiosyncrasies of the patient. *Breakfast* : Lean ham (3 oz.) or liver (2 to 3 oz.) or kidney with, if desired, one egg. Large slice of wholemeal toast, or two pieces of Vitaweat. Butter. One apple, pear, or orange. One large cup of weak tea, or one large cup of coffee and milk (equal parts). *Lunch* : Sardines (oil to be discarded) 2 oz., or liver (2 oz.), or fresh fish (3 oz.) or chicken (3 oz.). Plain cheese. Salad (lettuce, tomatoes, beetroot, etc.). Wholemeal toast or Vitaweat as for breakfast, with butter. Apple, pear, or orange, or stewed fruit. One glass of water. *Afternoon* : One glass of milk. Piece of plain cake. Fruit. *Dinner* : Three oz. of lean meat, or fresh fish, or chicken; or 1½ oz. of fish and 1½ oz. of meat or chicken. Vegetables as desired (all greens, carrots, parsnips, turnips, onions, leeks, etc.). Wholemeal toast or Vitaweat as above. Fresh fruit. One glass of water, tonic water, or weak whisky and soda. *Avoid or restrict* : Sugar, jam, marmalade, honey, sweets, pastries, puddings, rich cakes, soups, fats (except butter as allowed), pork, bacon, sausages, strong tea and coffee, beer, wines. *Notes* : Liver should be

taken on at least three days a week if possible. One glass of milk and at least one salad should be taken daily. The menus for lunch and dinner may be transposed if desired. The fluid intake should be restricted to that indicated above, unless thirst is experienced, when more may be taken. Glucose in powder should be substituted as far as possible for ordinary sugar.

✓ Calcium salts, *e.g.* the gluconate, chloride, carbonate, lactate, or the compound calcium-sodium-lactate, should be given. They have a diuretic effect and lessen the tendency to serous exudation. It may be advisable to prescribe them in combination with ergosterol for a while. -

Often some method of desensitisation is necessary. Peptone taken orally one hour before each meal is occasionally efficacious, but it is preferable to give it in increasing doses by intravenous or intramuscular injection every three to seven days. Autohæmo- and autoserotherapy are often successful, but the blood should, if possible, be withdrawn just before the outbreaks of urticaria occur. Injections of the substance P. of Oriel have been successful in some cases in which other methods have failed. -

Lastly the effect of physical exhaustion and psychical disturbances as predisposing factors in urticaria, as in other allergic conditions, must not be forgotten. A complete rest, followed by a change of surroundings, or judicious psychotherapy may succeed when all other means have failed.

URTICARIA PIGMENTOSA

Under this term are included two types of eruption, which are clinically, and in all probability ætiologically distinct. They are usually referred to as the juvenile and adult types.

Juvenile Type. The eruption consists of round or oval macules and papules, the colour of which varies from light fawn to dark brown. They tend, when numerous, to lie with their long axes in the lines of cleavage. The pathognomonic sign of the disease is that the lesions, when vigorously rubbed or scratched, become reddened, swollen, and form urticarial wheals. The majority of cases are accompanied by itching, and dermatographism is frequently seen. The disease usually begins in early infancy, and often disappears or becomes much less evident at puberty; it may, however, persist indefinitely, and its first appearance may be delayed until puberty or even adult life. Most of the lesions are situated on the trunk and buttocks, but the limbs and head may be involved. Histologically there is cedema of the cutis, as in ordinary urticaria, increased pigmentation in the deeper layers of the epidermis, and a dense infiltration of *mast cells*, which is absolutely characteristic of the disease.

Adult Type. The lesions are macules or slightly elevated papules of a characteristic reddish-brown colour, sometimes with a tint of lilac. On the whole they tend to be smaller than those of the juvenile type. They occur most commonly on the anterior surfaces of the forearms and on the trunk, and may be sparsely scattered or present in large numbers over a wide extent. As in the juvenile type, friction causes them to become urticated, but usually to a far less degree. Histologically mast-cells are found in the dermis, but are relatively few in number.

Ætiology. *Juvenile Type.* The condition is commoner in males than in females, and may be familial. Some authors incline to regard it as related to the leukæmias, in view of the fact that, apart from the enlargement of the liver, spleen, or lymphatic glands noted in certain cases, blood-changes have been observed of the lymphocytic or oftener the myelocytic type. This view is, perhaps, in accord with the characteristic mast-cell infiltration of the skin.

Adult Type. This may probably be regarded as a chronic form of urticaria. Its appearance may be preceded by attacks of ordinary urticaria, and has been known to follow food-poisoning. Further research along biochemical lines would probably decide its relationship to the allergic group of eruptions.

Treatment. The lesions in the juvenile type can be made to disappear by freezing with carbon-dioxide snow, but the treatment must be prudently applied in view of the fact that it has in some cases provoked a nitritoid crisis.

PRURITUS AND PRURIGO

The word *pruritus* merely indicates the symptom of *itching*, which may be idiopathic in the sense that it is not the result of any visible change in the skin, or may be one of the subjective manifestations of a definite eruption. Under the term *prurigo* are included a variety of clinical entities, in which pruritus is the cardinal symptom, but certain characteristic lesions also occur in the skin, either primarily or as the result of scratching and rubbing. Thanks to histological researches (43), we can now distinguish between these primary and secondary lesions in the different forms of prurigo.

PRURITUS

The sensation of itching is as indefinable as those of taste, smell or touch. It is not known for certain whether the sensory nerves of the skin are concerned in its production, or whether, as seems more likely, it is a manifestation of involvement of certain fibres of the autonomic nervous system. It will be remembered that one of the earliest symptoms of experimental anaphylactic shock in animals, in which there is a profound disturbance of the vegetative nervous system, is violent itching, and the same is true of conditions comparable to anaphylactic shock, such as serum sickness, urticaria, and certain forms of prurigo. The degree of itching varies from a mild and even pleasurable sensation, as that provoked by tickling, to the terrible paroxysms in which the unfortunate victims lose all control, and tear their skin unmercifully in an attempt to obtain relief. Pruritus may be more or less generalised or localised to certain areas, and as a rule it is paroxysmal. In the idiopathic forms, the prurigos, and that accompanying scabies or pediculosis corporis, it is usually nocturnal.

Ætiology. The causes of pruritus are very numerous, but may tentatively be classified after Darier as follows :—

Pruritus of External Origin. Under this heading may be included the itching provoked by mechanical means (tickling, contact with certain materials, such as wool, etc.), and by physical or chemical agents ; by the activity or bites of animal parasites, *e.g.* lice, bugs, acari, oxyuris ; and contact with certain plants, *e.g.* the nettle, or animals. Such itching may be regarded as physiological and purposive, since by scratching the irritant in question may be removed, but, even so, the degree of itching varies greatly according to the individual affected. *Infection of the skin* either by bacteria or the higher fungi may also in certain situations be the cause of a localised pruritus. This is particularly the case at muco-cutaneous junctions, and in the natural folds of the skin. Thus many cases of pruritus ani or vulvæ are due to infection of the parts with pyogenic cocci, particularly a streptococcus, and with ringworm fungi or monilia ; and infection with these organisms is the cause of intertrigo of the folds, which may be accompanied by severe pruritus. *Pruritus in Certain Eruptions.* A large number of eruptions may be accompanied by itching, some constantly, others occasionally. As examples of those in which pruritus is almost invariably present in some degree may be cited : urticaria, eczema, lichen planus, dermatitis herpetiformis, acne necrotica, and the premycotic stage of mycosis fungoides. It is a remarkable fact, however, that in lichen planus the itching may be so severe as to render the patient almost insane, or it may rarely be entirely absent. In psoriasis and the syphilides it is seldom present, but in the former it may occasionally be considerable. It is therefore clear that pruritus is often more dependent on the individual affected than on the eruption with which it is associated. *Toxic Pruritus.* Under this

heading may be considered the pruritus that is provoked by certain drugs, either when given by mouth or by injection, *e.g.* belladonna, morphine, cocaine, caffeine, the barbitone group of hypnotics, and certain arsenical preparations; by foodstuffs, even without urticaria; and by the toxins of animal parasites, such as the intestinal worms and hydatids. As regards drugs and foodstuffs, personal idiosyncrasy, or, more accurately, the question of sensitisation, is of paramount importance. *Autotoxic Pruritus*. The term autotoxic implies that the substance or substances to which the pruritus is due are of endogenous origin, their presence in the blood being dependent on some error of metabolism, the existence of certain organic diseases, or of a source of toxic absorption. It is impossible in the present state of our knowledge to state exactly the nature or composition of the actual substances responsible for the pruritus in cases belonging to this group. The question will be more fully discussed in the section dealing with the prurigos. *Diabetes*, or simple hyperglycæmia, is frequently associated with pruritus, which may disappear when, under suitable treatment, the blood sugar is reduced to normal limits. It is, however, by no means a constant symptom, nor is it certain that the excess of sugar in the blood is the cause of the pruritus. A localised pruritus of the genitalia in both sexes, associated with an infective dermatitis usually caused by a monilia, may be due to the passing of saccharine urine. *Renal disease*, particularly chronic interstitial nephritis and the arteriosclerotic form, is another predisposing cause, and pruritus, with or without a concomitant eruption, may herald an approaching uræmia. *Jaundice* is almost always accompanied by severe itching, due to the presence of bile-salts in the blood, and a high *cholesterinæmia*, which may be associated with xanthoma, is sometimes found in patients with pruritus. It is notorious that *gouty* persons tend to itch, and this symptom may promptly be ameliorated by a suitable dietary and other measures designed to reduce the uric acid content of the blood. *Constipation* is also an apparent factor, and many cases are relieved by intestinal lavage and aperients.

Various researches (44) upon the increased irritability of the skin, provoked by a deficiency of calcium, suggest that a disturbance of the normal equilibrium of mineral salts in the blood and skin may sometimes be causative. The rôle of certain disorders of the *endocrine glands* is difficult to evaluate, but pruritus is common in Grave's disease, and in women after ovariectomy or at the menopause. *Focal sepsis* is certainly responsible in some cases, and dramatic cessation of either a general or localised pruritus may follow removal or treatment of a chronic source of infection. In lymphadenoma and the leukæmias pruritus may also be a distressing symptom, and may occur with or without actual cutaneous lesions. Lastly must be considered what may be called the *psychological* factor in pruritus, since the degree of itching varies greatly in different cases, and in idiopathic pruritus the patient is usually highly strung and prone to worry unduly. Both in generalised pruritus and in the local form, which in time develops into circumscribed prurigo (*q.v.*), this psychological element is usually apparent. In pruritus localised to the genital organs, particularly in women, it may be the predominant, if not the only causative factor. In many such cases careful inquiry will elicit a story of unrequited love, a broken-off engagement, or unhappy marital relations. Such an explanation must not, however, be assumed until all other possible causes, for example, a local bacterial or mycotic infection, or a reflex source of irritation, have been considered.

The special characteristics and the treatment of certain regional forms of pruritus, *e.g.* pruritus ani, will be considered in the next section.

PRURIGO

The term *prurigo* is used to designate those cases of idiopathic pruritus, either general or local, in which characteristic changes take place in the skin of the affected parts, and also certain clinical entities or syndromes that may be distin-

guished by their primary and secondary lesions, by the distribution of the sites involved, by seasonal, racial, or age incidence, and by their relationship to accompanying symptoms or diseases. These latter comprise prurigo simplex acutus (urticaria papulosa, lichen urticatus, strophulus), the prurigos of Besnier and Hebra, prurigo nodularis, prurigo senilis, prurigo æstivalis and hiemalis, and the prurigos of lymphadenoma and leukæmia. In considering the cutaneous lesions associated with the various forms of prurigo, we have to distinguish between those that result from scratching and rubbing, and those that are primary. Civatte's histological studies indicate that in urticaria papulosa, the prurigo of Hebra, in summer prurigo, and in some cases of lymphadenoma, there are primary papular lesions, arising independently, but subsequently altered by scratching: whereas in the simple prurigo that complicates a general or local pruritus, and in other forms, the visible changes in the skin are due entirely to scratching and rubbing.

Symptoms. The *immediate* effect of scratching by a normal person on healthy skin is to produce a fugitive erythema, which may be accompanied by serous exudation, so that a wheal is formed (dermographism); this reaction is due to the liberation in the skin of a histamine-like substance in response to injury. In eczematous subjects, in whom the epidermis is in a sensitised state, continued scratching of a healthy area of skin may of itself give rise to an eczematous reaction (traumatic eczema). The later effects are of two types. In one the patient's nails tear away pieces of epidermis, producing the familiar "scratch-marks," illustrated by scabies, pediculosis corporis, dermatitis herpetiformis, and the prurigo of Hebra. In the other group there may be no such visible signs of scratching, *e.g.* in lichen planus, pruritus senilis, urticaria and pediculosis pubis.

Civatte has shown that in slight excoriations, produced by scratching, the early changes take place in the *lower* layers of the epidermis and in the papillary body; in deeper excoriations there is a crust formed by a mass of coagulated serum, infiltrated with leucocytes and red corpuscles, which is embedded in the epidermis. Beneath it the horny layer and granular layers—and at its centre the whole epidermis—are absent. From this it is clear that moderate scratching perforates the healthy epidermis *from the depth towards the surface*. Some scratch-marks are punctate and situated at the summits of the *follicles*, which in pruritus are often retracted by contraction of their pilomotor muscles; these excoriated follicular papules, which are well seen in scabies, must not be confounded with the true papules of prurigo. In other cases, as, for example, in pediculosis corporis, the scratch-marks are linear, and independent of the follicles.

Apart from excoriations, however, there are two types of lesion that result from long-continued scratching, namely *prurigo papules* and *lichenification* (*lichenification* of Besnier). These two forms of reaction to scratching often coexist in the same patient.

(1) The *prurigo papule* varies in size between that of a millet seed to that of a pea: on the whole it tends to be larger than the elementary papule of lichen planus. Usually hemispherical, it may, like the latter, be plane. Its colour varies, being sometimes almost that of the normal skin, sometimes reddened or bluish-red, or yellowish-brown. Its surface may be smooth and shiny, or scaly: often it is excoriated from scratching and covered with a blood-crust. Histologically these papules are characterised by acanthosis of the epidermis, with hypertrophy of the granular and horny layers, and an infiltration of the dermis with leucocytes and eosinophiles.

(2) *Lichenification*. This change in the texture of the skin, due to repeated scratching over long periods, has been minutely described by Brocq. It may be more or less generalised, or strictly localised to certain regions (circumscribed prurigo, lichen simplex chronicus of Vidal). The skin of the affected part is markedly thickened, and the natural lines are accentuated, thus giving the picture of a mosaic, composed of lozenge-shaped, polygonal, or square areas, the

surfaces of which appear polished and shiny. Sometimes, however, they may be covered with fine scales, or, after the paroxysms of scratching, by blood-crusts. The colour of lichenified skin varies. In quiescent periods the area affected often only differs from that of the surrounding healthy skin in being slightly more pigmented: sometimes it is dark-brown or greyish-brown, sometimes even depigmented, but after a paroxysm it is usually reddened and excoriated. At the edges of a patch of lichenification there is almost always a zone of brownish pigmentation, which merges imperceptibly into the healthy skin beyond; in this zone are often seen small discrete shiny papules, flat and hardly raised above the surface. This state of lichenification may arise *de novo* on normal skin as a result of the scratching and rubbing provoked by a pruritus, or it may complicate a pre-existent dermatosis, such as eczema, seborrhœic dermatitis, intertrigo, or lichen planus, which is then said to be *lichenified*. It is often difficult in a given case to distinguish between a primary prurigo, which has become *eczematised*, and a primary eczema, which has become *lichenified*. To such cases the non-committal term "eczema-prurigo" is often applied.

The different forms of prurigo, as met with in practice, may now be dealt with.

Prurigo Simplex. The term *prurigo simplex* (excluding *prurigo simplex acutus* or papular urticaria of young children) should strictly be reserved for those cases which do not fall into the special categories to be described later, and in which the earliest symptom is an idiopathic pruritus, *i.e.* one neither dependent on a recognisable external cause, such as invasion by animal parasites, a mycotic or bacterial infection, nor resulting from intoxication by drugs or foods. In describing the localised forms of prurigo simplex, however, it is more convenient to include pruritus ani and vulvæ, which may depend on a purely local cause.

Circumscribed Prurigo (Lichen simplex chronicus of Vidal, Neurodermatitis). The characteristic changes in the affected area of skin are those of *lichenification* (*q.v.*). The sites of election are the occipital region of the scalp (this localisation is almost confined to women), the back or sides of the neck, the antecubital fossæ, the elbows and upper portion of the posterior surface of the forearms over the ulna, the outer surfaces of the thighs and legs, the popliteal spaces, the genital organs and groins, the sacral and coccygeal regions, the internatal cleft and perineum.

The early symptom is a simple pruritus, intermittent and at first often slight; gradually the itching becomes more intense, until veritable paroxysms, usually nocturnal, occur, and the patient scratches or rubs the part furiously. This may be done unconsciously during sleep, until the crisis wakes him.

When fully established, a patch of circumscribed prurigo presents three zones: an ill-defined, hardly thickened outer one of pigmentation, with some exaggeration of the natural lines and some discrete shiny plane papules or "facets": a middle one in which the natural lines are more exaggerated, the intervening portions of skin taking the form of papules, shiny and excoriated: and a central one, in which these changes of lichenification reach their maximum, infiltrated, hyperpigmented or depigmented, and scaly or macerated, according to the region involved. Often one cannot distinctly recognise these zones. On parts such as the eyebrows, the axillæ, the pubis and the extensor surfaces of the arms and legs, the hairs become worn away by the constant rubbing, and stand up stark and straight like the bristles on a brush.

A patch may last for years, the infiltration increasing with time. Sometimes new ones arise, the older ones ceasing to itch and undergoing resolution, leaving an area of pigmentation. Not only is there usually an associated hyperpigmentation of the surrounding skin, but circumscribed prurigo is frequently seen in patients with vitiligo. Although the objective appearances of a patch of circumscribed prurigo are those of lichenification, already described, in pruritus ani and vulvæ they are modified owing to the special structure of the parts.

In pruritus ani the area affected usually corresponds roughly to the corrugator

cutis ani muscle, but extends sometimes actually into the rectum. In men the itching often spreads forward to the median raphe of the scrotum, and in women to the vulva. In some patients, though their pruritus be severe, there may be but little objective change in the perianal skin. As a rule, however, this is thickened, sodden, whitish in colour, and thrown into infiltrated folds, between which are often found superficial fissures. Sometimes the surface is inflamed, eczematised and crusted. In long-standing cases atrophic changes are apt to occur, and the skin becomes pale and dead-looking, like old parchment.

In *pruritus vulvæ* the pruritus may be strictly localised to the upper portion of one or both labia majora, which becomes lichenified, or, more commonly, the labia majora and minora and the part surrounding the clitoris are all affected. As a result of long-continued scratching, the parts become thickened and hypertrophied; they may be dry or sodden, or excoriated, eczematised and crusted. Frequently the skin of the mons veneris, groins, and inner surfaces of the thighs presents the typical appearances of lichenification, and the pruritus spreads downwards to the perianal region. As in pruritus ani, atrophy is likely to supervene in chronic cases, particularly in elderly women, and the appearances simulate those of kraurosis vulvæ.

Histologically the changes in the lichenified skin of circumscribed prurigo are far less apparent than would be expected. There is some cell-infiltration in the papillary body, with acanthosis and lengthening of the interpapillary processes in the epidermis.

Diffuse Simple Prurigo. In cases of more or less generalised pruritus there may be surprisingly little change in the skin, even though the pruritus be of long standing. On the other hand, there may be a variety of visible lesions—discrete prurigo papules, extensive areas of lichenification, linear scratch-marks, excoriated follicular papules, and eczematization. The skin as a whole tends to become harsh, dry, thickened, and pigmented: in some patients the pigmentation is so intense, particularly around the neck and in the flexures, as to recall that of Addison's disease.

As in the circumscribed form, the paroxysms of itching are periodical; although they may occur during the daytime, usually as a result of emotional stress, undue exertion, a change from a cool to a warm environment, or *vice versâ*, they most commonly begin in the evening when the patient is tired, when he undresses at bedtime, or in the early hours of the morning.

Treatment. Successful treatment both of the local and general forms depends entirely upon investigation of the individual case. External provoking factors, and the diet, mode of life, psychological state, and the metabolism, as revealed by examination of the urine and blood, of the patient must be considered; and sources of toxæmia, such as focal sepsis and excessive intestinal putrefaction, should be sought for. In the generalised form, and in some cases of circumscribed prurigo, apart from suitable general and local treatment, one of the various methods of desensitisation may be indicated, *e.g.* intravenous or intramuscular injections of peptone, and autohæmo- or autoserotherapy.

Local treatment is chiefly of value in the circumscribed variety, and the application of crude coal-tar, or radiotherapy usually gives the best results. The former, previously washed to remove excess of alkali, may be painted on neat, allowed to dry, and then powdered; or it may be diluted with acetone-collodion, or prescribed in a paste. Radiotherapy is invaluable, both as an antipruritic, and for causing resolution of chronic infiltrated patches of lichenification, but disastrous results have occurred from too frequent applications. In generalised pruritus, except in those cases in which it is associated with excessive dryness of the skin, as for example from the excessive use of alkaline soaps or other defatting substances, local treatment has a purely palliative effect, but cooling lotions or creams containing phenol, menthol, and tar, may cause a temporary cessation of itching and enable the patient to sleep.

The local treatment of *pruritus ani* and *p. vulvæ* demands a thorough investigation of the cause ; for example, intestinal worms, hæmorrhoids, fissures, dyschezia, and infection of the parts with bacteria or fungi. Glycosuria must always be excluded in cases of *pruritus vulvæ*. It predisposes to infection of the parts with a monilia, which may produce an acute eczematous dermatitis. It cannot be too strongly emphasised that radiotherapy should never be employed until the most likely cause has been determined, and then only after other measures have failed. Many causes of *pruritus ani* are due to an intertrigo of the inter-natal cleft, caused either by infection with a streptococcus, accompanied by streptococcal fissures, or with the epidermophyton or a monilia, and appropriate treatment by painting with diluted tincture of iodine or a solution of silver nitrate, or by rubbing in a benzoic-salicylic or sulphur-salicylic ointment, will be curative ; in women it is commonly secondary to a vaginal discharge, due often to a chronic cervical infection, and in every case an expert pelvic examination should be insisted upon. In some case of *p. ani* and *p. vulvæ* no local cause can be found, and the possibility of a psychical origin should be considered. Both in cases due to an infective intertrigo, and in others, one of the most valuable local applications is a crude coal-tar paste, which should be applied thoroughly at night time, a simple paste or dusting-powder being substituted during the day.

PRURIGO SIMPLEX ACUTUS

(*Urticaria papulosa. Lichen urticatus. Strophulus.*)

This eruption is met with almost exclusively in young children between the ages of one and eight years, but occasionally it is seen later, or even in adolescence. Ordinary urticaria is very rare in infants. The eruption consists of bright red urticarial lesions in the centre of which is a small indurated papule, which persists after the surrounding erythema and oedema have subsided, so that a number of these small, shotty, brownish papules may be seen mixed with recent urticarial wheals. The rash causes intense irritation, and, as it is apt to be most profuse in the evening, the child often lies awake at night scratching and rubbing himself ; during the day-time itching may be absent or slight. As a result of scratching the papules become covered with small blood-crusts, and secondary infection with pyogenic cocci occurs, resulting in the formation of pustules, impetiginous lesions, and sometimes ecthymatous sores. The eruption may then imitate that of scabies very closely. Sometimes exudation may be so great that actual vesicles are formed, or very rarely bullæ, and this vesicular form of papular urticaria is not infrequently mistaken for chicken-pox.

In chronic cases the papules, conical at first, are apt to become flattened, shiny, and angular, and they frequently have a central pit ; they may thus resemble the papules of *Lichen planus* very closely. Indeed, cases that have been thought to be examples of *Lichen planus infantum* have later proved to be really *Urticaria papulosa*, although true *Lichen planus* does very occasionally occur in young children. In some children acute attacks of papular urticaria occur occasionally, usually in summer-time, and between the attacks there is absolute freedom from the eruption ; in others the disease is chronic, acute exacerbations appearing from time to time. It is usually, however, most severe in hot weather. As a rule it does not continue beyond the age of seven or eight years.

Ætiology. Like ordinary urticaria and the chronic forms of prurigo, papular urticaria is one of the cutaneous manifestations of the allergic state. It is met with in two distinct types of children—the fat, or, perhaps, more strictly the “watery,” indolent, often rickety child with a tendency to chronic catarrh of the mucous membranes and offensive stools from excessive putrefaction, and the thin, nervous, emotional child. Not infrequently other allergic symptoms may precede, coincide with, or follow papular urticaria, as described under the prurigo

of Besnier. The actual eruption must usually be due to an antigen, which, reaching the sensitised skin, provokes a characteristic reaction in the dermis, upon which the elementary lesion, the papule, depends. It is probable that in the majority, if not in all cases, the source of the antigen is the alimentary tract, as in Besnier's prurigo. Clinical experience suggests that the antigen is not specific for the disease, but may rarely be so for the individual, for in the majority of cases no evidence of specific food-sensitiveness can be obtained, but occasionally one food, and one only, is found to provoke the attacks—for example, bananas or eggs. A very striking feature of the disease (45) is that the eruption disappears promptly when the child is admitted to hospital, cannot be reproduced there, but reappears when he returns home. This, however, is to a certain extent true of other allergic diseases. Threadworms often thrive in the unhealthy catarrhal bowel of urticarial children, and it has been suggested that the worms may produce the antigen. There is a diminution of the serum calcium, and administration of calcium salts has been advocated. Teething has been considered an important ætiological factor, and it is likely that the nervous unrest and sleeplessness that accompany it, by reacting on the digestive system of sensitised children, favour the absorption of antigen and so provoke the attacks: one cannot, however, exclude the possibility of a direct effect by reflex irritation.

Morbid Anatomy. Apart from impetiginous or pustular sores, due to a superadded pyogenic infection resulting from scratching, the lesions of papular urticaria are three in number—the urticarial wheal, the central papule, and more rarely, the vesicle or bulla. Of these, the papule is the most characteristic. It is formed by an œdema of the dermis, accompanied by an infiltration with lymphocytes around a vessel: this infiltration follows the course of the vessel from its origin in the dermis up to the corium and in its ramifications in the papillary body. This vessel forms the axis of the papule, the acuminate form of which is explained by the cellular infiltration, which spreads out at its summit, and is comparable to a nail plunged vertically in the dermis. Apart from the lymphocytes, there is an infiltration of the corium with eosinophile leucocytes, both around the vessels and distant from them.

In some papules these changes in the dermis are found alone, but in the majority the epidermis is involved. The epidermic lesions appear due entirely to scratching, and vary according to the degree of traumatism; there may be merely a slight œdema of the malpighian layers with mononuclear exocytosis, or a definite cleavage of the malpighian body with the formation of an intra-epidermic vesicle, the roof of which is constituted by the intact horny layer and upper malpighian layers, the floor by the lower part of the rete, or finally by a bulla resting directly on the papillary body, which becomes replaced by a serous crust. The large bullous lesions, sometimes met with in papular urticaria, occur chiefly on parts where the horny layer is thick and less likely to be ruptured.

Diagnosis. The disease has to be distinguished from scabies, Hebra's prurigo, varicella, and *Lichen planus*. From scabies the diagnosis may be difficult, but burrows can almost invariably be found in children with scabies, if carefully sought for. Hebra's prurigo chiefly affects the lower extremities, avoids the flexure surfaces, and is usually accompanied by inguinal adenitis. Careful observation should always prevent confusion between bullous *Urticaria papulosa* and chicken-pox: *Lichen planus* is extremely rare in children, and the papules are not preceded by urticarial wheals.

Treatment. Successful treatment depends largely on the investigation of the individual case. The stools should be examined for threadworms, excess of mucus, and undigested foods, and also bacteriologically. In the fat, pasty, catarrhal child, cane-sugar and soft starchy foods, particularly ordinary bread and milk puddings, should be excluded from the dietary: lactose or glucose should be substituted for cane-sugar, and farinaceous foods given in a form that necessitates thorough mastication. In the thin, nervous child, whose stools

usually reveal excessive putrefaction, meat and fish should be excluded or reduced to a minimum, and a dietary prescribed containing plenty of crisp farinaceous food, vegetables, cooked fruits, and lactose or glucose. Careful enquiry must be instituted as to whether any particular foods, such as bananas, acid fruits or eggs, appear to provoke the attacks, and, if necessary, cutaneous food tests should be made.

Internally, small doses of calomel or grey-powder at night time and mist. alba dm. i—oz. $\frac{1}{2}$ should be prescribed for a few days, or an alkaline bitter mixture, containing the compound tincture of rhubarb, given half an hour before the three principal meals. After this preliminary treatment, calcium lactate in the form of syr. calcii lactophosphat. is often of great value. The temporary use of a chloral and bromide mixture at night time is justifiable in severe cases. Peptone in the form of peptonal or peptamine, given one hour before meals, appears sometimes to be successful. The clothing should be light and porous, and the child be kept out of doors as much as possible. Real or artificial heliotherapy is invaluable in obstinate cases. During the attacks a warm bath, to which 1 or 2 oz. of liq. picis carbonis may be added, should be taken in the evening, and the skin afterwards powdered with warmed starch powder. If septic infection of the skin has resulted from scratching, boric baths and a boric or weak mercurial ointment will control it.

PRURIGO OF HEBRA

(*Prurigo ferox vel agria*)

This form of prurigo, first clearly described by Hebra, presents such characteristic features that, like the prurigo of Besnier, it must be regarded as a well-defined clinical entity. Unfortunately, although absolutely distinct, these two varieties have been confused. Hebra's prurigo, which is rare, begins, as a rule, in early childhood from the second to the fifth year: whether it sometimes supervenes upon ordinary papular urticaria is doubtful. The elementary lesion is a papule, which differs both in its clinical and histological features from that of papular urticaria. When unaltered by scratching, this papule is small, very hard, and dry; it is felt by the touch more easily than it is seen, for it projects but little, and hardly differs in colour from that of the skin in which it appears embedded. Under the influence of scratching, however, it becomes excoriated, and its character is masked by an overlying blood-stained crust, which, on separating, may leave a small scar.

When fully established, the disease presents a characteristic picture. The affected parts of the skin are chiefly the extensor surfaces of the limbs, the thighs and legs more than the arms, and to a less extent the trunk and face. The joint flexures are spared, in contradistinction to the prurigo of Besnier, as also are the palms and soles. As a result of the long-continued and violent scratching, the skin of the sites involved becomes harsh, thickened, and deeply pigmented. It is covered with excoriations, some linear, some pin-point and follicular; the elementary papules can be distinguished, but are surmounted by crusts, and mingled with them are the whitish scars of former lesions. Secondary eczematization or impetiginisation are common, and deep ecthymatous sores may complicate the picture. The lanugo hairs become worn by the scratching, and either stand up like short bristles or disappear entirely. On the less-affected parts of the skin there is seen the follicular erection found in other forms of prurigo, and due to the contraction of the pilo-motor muscles. The inguinal and, to a less extent, the axillary glands are enlarged. The characteristic changes in the skin and the distribution make it possible to diagnose the condition with the eyes shut, by passing the hands over the patient. A considerable degree of eosinophilia in the blood is present. The victims of this variety of prurigo are poorly nourished, apprehensive, and ill-cared for; the constant irritation and consequent loss of sleep react upon both their physical development and their mentality.

There is a relatively mild form of the disease (prurigo mitis), in which the elementary papules and the distribution are identical, but the secondary excoriations, lichenification, and pigmentation are less evident, and the glandular enlargement slight.

Ætiology. Hebra's prurigo is more frequent among boys than girls. It would seem that race, since it is commonest in central Europe, and poverty are the predominant predisposing factors. That it is an allergic manifestation, comparable to papular urticaria and Besnier's prurigo, is certain, but it is not known whether the antigen responsible is specific, or whether the disease, like urticaria, is a special form of cutaneous reaction to a variety of antigens. In one case ascarides appeared to be the source. The writer, confirming the observations of other authors, recently admitted a case to hospital, and, although no treatment of any kind was ordered, the prurigo ceased at once, and at the end of a week the skin had undergone a remarkable change for the better. Relapse occurred at once on his return home.

Morbid Anatomy. As in papular urticaria, the essential lesion is a papule, in which the primary changes are dermic, those in the epidermis being secondary to scratching. The initial papule is formed by a dense infiltration of the corium with *polymorphonuclear* leucocytes, which undergo rapid degeneration after leaving the blood-vessel. This mass of degenerate leucocytes forms the centre of a more diffuse infiltration of polymorphonuclear cells, which occupy the whole corium and the papillary body, but these cells do not show degenerative changes. Among them one finds a few lymphocytes around the vessels. There is a little or no œdema, but some proliferation of fibroblasts. The epidermal changes vary in different cases. They may be those of diffuse lichenification, or the necrosis of the malpighian layers, with cavitation, already described in papular urticaria.

Diagnosis. This presents no difficulties, the distribution, the pigmentation, the excoriated harsh skin, and the associated glandular enlargement being characteristic. It will be noted that the antecubital fossæ and popliteal spaces, which are the sites of election in the prurigo of Besnier, are spared.

Treatment. The essential treatment, in the present state of our knowledge, is to remove the child from its home surroundings, and to send it to live an out-of-door life in the country on a generous mixed dietary. Hebra regarded the condition as incurable, and this may be so if the child is compelled to remain at home, but the writer has not seen a case in which the prurigo did not rapidly cease on removal to hospital.

PRURIGO OF BESNIER

This form of prurigo is a well-defined clinical entity, of particular interest to general physicians owing to its frequent association with asthma and other manifestations of the allergic state. A considerable proportion of patients are *ichthyotic*, and in a still higher proportion the condition has been preceded by *infantile eczema* of the allergic type.

The life-history of the patient is frequently as follows :—Soon after birth may be apparent the dryness of the skin, which heralds the ichthyosis that is not as a rule well marked until two or three years of age. In the first few months, but sometimes later, appears infantile eczema, the onset of which may coincide with a change from breast-feeding to a diet of cow's milk, or may almost immediately follow *vaccination*. At about the age of two years the eczema tends to change its characters and distribution. It leaves the face and head, the trunk, and the extensor surfaces of the limbs, and becomes, so to speak, concentrated in the antecubital fossæ and popliteal spaces, on the backs of the wrists and hands, and sometimes around the mouth and in the folds of the neck and groins. Constant rubbing and scratching leads to *lichenification* of the skin in these situations, and the clinical picture of Besnier's prurigo is established. Sooner or later *asthmatic* attacks, often diagnosed erroneously as bronchitis, and other allergic

manifestations supervene (*q.v.*). The symptoms of this hypersensitiveness, or state of allergy, vary according to the particular structure or tissue that is sensitised.

The majority of children with Besnier's prurigo are thin, pale, nervous, restless and introspective, but it may be seen in the fat, indolent child with signs of hypothyroidism. In a characteristic case the skin is ichthyotic, harsh, and of a curious sallow, greyish tint. The pilo-sebaceous follicles of certain areas stand out owing to contraction of the pilo-motor muscles, as in other forms of prurigo. Although the itching may be widespread, it is most intense in the antecubital fossæ and the popliteal spaces, on the backs of the wrists and hands, the dorsal surfaces of the ankles, around the mouth, on the forehead, particularly over the eyebrows, in the folds of the neck, in the groins and on the genitals, and sometimes over the elbows and knees; in many cases it is confined to the antecubital and popliteal regions. The skin at these sites exhibits the changes already described as *lichenification*; after a paroxysm of itching, eczematization with serous oozing, fissuring, and sometimes secondary impetiginisation are seen, but in intervals of comparative calm simple lichenification with pigmentation constitutes the sole objective signs. The pigmentation, however, is not confined to the lichenified areas, but may be generalised, and so intense, for example on the neck, round the eyes, and in the flexures, as to resemble that of Addison's disease, and, like it, may be accompanied by a low blood-pressure and muscular hypotonia.

The vermillion borders of the lips are usually of a greyish-blue or lilac tint, as is seen also in cases of light-sensitiveness. The muscular hypotonia is revealed by the faulty stance adopted when the child stands upright. The front of the chest is flat, and descends in an inclined plane towards the protuberant lax abdomen, the point of maximum projection forwards being just below the umbilicus: the back is arched, the scapulæ winged, and there is lordosis. The child is usually apprehensive, restless, easily exhausted, and extremely sensitive to its surroundings and to the influence of those with whom it comes in contact; the same is true of the adult cases. The paroxysms of itching or the attacks of asthma, which begin, as a rule, in the evening or at night time, are often provoked by an emotional upset or the anticipation of some displeasing prospect, and may cease automatically in the quiet and well-ordered routine of hospital life, only to return under the disturbing influence of home surroundings.

Ætiology. One of the most striking features of Besnier's prurigo and of the other manifestations of the allergic state, with which it may be associated, is their hereditary transmission and familial incidence. Enquiry will almost always reveal the presence of ichthyosis, hay fever, or asthma in the parents and near relatives, or a history of infantile eczema, cyclical vomiting, urticaria or prurigo in their childhood.

Recent researches have done much to explain the pathogenesis of Besnier's prurigo, and of all the forms of prurigo it is the one of which we possess the most exact knowledge. It is clearly due to sensitisation of the skin to antigens, which, as in many cases of urticaria and probably in Hebra's prurigo, are usually, if not always, derived from the alimentary tract, escaping fixation and destruction in the liver. In urticaria, simple prurigo, and Hebra's prurigo, the reaction, resulting from contact of antigen with the sensitised skin, takes place primarily and essentially in the dermis, whereas in eczema and Besnier's prurigo, it is epidermo-dermal, *i.e.* both the dermal tissue (probably neuro-vascular) and the rete Malpighii are sensitised.

As regards the nature of the antigens, it is probable, as was pointed out in the section on urticaria, that the actual antigenic substances, although derived from proteins, are themselves non-protein in nature and of relatively simple composition. Persons manifesting the abnormal hypersensitiveness that results in the multiple symptoms of allergy referred to would seem to have a limited power of dealing effectively with foreign proteins, both when taken into the alimentary

tract or when they reach the system parenterally. In the case of food-proteins, it is probable that their delayed or incomplete digestion is an important factor, and diminution or lack of gastric hydrochloric acid has been noted in a considerable percentage of these persons; apart from this, the failure of the liver to fix and destroy proteins and their derivatives, including their antigenic moiety, is clearly the essential factor. When this function of the liver fails, antigens reach the blood-stream and react with the antibodies in sensitised tissues, of which the skin is the most important, and these reactions, represented by the cutaneous manifestations of the allergic state, are really protective in nature, since they result in the fixation and destruction of the circulating antigens. In other words, the skin, and, to a less extent, other tissues take on a vicarious protective function when that of the liver fails.

In infantile eczema, and possibly in Besnier's prurigo, it would seem likely that sometimes, as in certain cases of urticaria, the antigen responsible is specific in that it is derived from one food-substance (*e.g.*, wheat, oat, cow-milk), but in the latter, at any rate, this is certainly exceptional. It is found (46) that in patients with Besnier's prurigo, one can evoke the hæmoclastic crisis by the oral administration of various proteins and peptones, or by injection of their own blood. Examination of the blood and urine reveals the same changes that characterise other manifestations of the allergic state (*q.v.*).

Apart from the factor of sensitisation, however, the importance of psychological disturbances can hardly be exaggerated in these patients. The asthma-eczema-prurigo syndrome is particularly likely to occur in the "only child." Rogerson (47) has clearly shown how the home environment may affect these children. Out of twelve severe cases, selected at random, five were entirely relieved of their symptoms by psychotherapy of the mother and, to a less extent, of the child itself, and in five others there was marked and progressive improvement.

Morbid Anatomy. The microscopical changes in a patch of Besnier's prurigo naturally vary. In the quiescent stage, they are merely those of lichenification, namely acanthosis and hyperkeratosis: during a period when the itching is severe, the lesions of eczematization—vesiculation—and of scratching, *viz.* rupture of the rete beneath an intact horny layer, or serous crusting when this is broken, are observed.

Diagnosis. Once a case of Besnier's prurigo has been seen and its salient features appreciated, there should be no further difficulty in diagnosis. From the prurigo of Hebra it is easily distinguished by the inverse distribution of the chief sites of election—extensor surfaces of the limbs in the former, antecubital and popliteal spaces in the latter. Moreover, the characteristic lesions in Hebra's prurigo are the papules, whereas in that of Besnier they are diffuse plaques of lichenification with eczematization.

Treatment. Besnier, in his original writings, emphasised the chronicity and resistance to treatment of the form of prurigo that now bears his name. ♂

Observations upon a large number of cases have confirmed the value of the following principles of treatment, based largely on biochemical researches (48); (1) The treatment *par excellence* is a completely out-of-door life in a fairly bracing climate with judicious heliotherapy: some cases do well by the sea, others are better among inland hills. The clothing must be light, and, as the physical condition improves, vigorous exercise should be taken. The influence of cool air and sunlight on the whole skin is potent in stimulating the accelerator endocrine glands, chiefly the adrenals and thyroid, and is doubtless an important factor in restoring the metabolism and endocrine-autonomic balance to normal. Under these conditions, even though no dietetic restrictions be enforced, the patient's whole appearance and temperament are transformed. His skin, even though previously ichthyotic, becomes soft and supple, and its horny layer thin and translucent. The prurigo and asthmatic attacks cease. The tone of the muscles

is restored, with consequent improvement of the stance and increased physical vigour, and the patient loses his irritability and apprehensiveness, and becomes calm, bright and happy. This physical and mental transformation is accompanied by a restoration of the metabolic functions to normal, as revealed by biochemical examinations of the blood and urine. Unfortunately, if the patient be compelled to return to a sedentary indoor life in unhealthy or unhappy home surroundings, relapse is liable gradually to occur. Psychological investigation and treatment, both in children and adults, may be of paramount importance. —

✓ (2) *Diet.* A lacto-vegetarian diet has been recommended, but the writer has recently observed that a dietary such as that recommended for the treatment of chronic urticaria is usually of great value in these cases. Foods to which the cutaneous tests reveal hypersensitiveness should, of course, be excluded.

(3) In some cases, a preliminary detoxication treatment is advisable. For this purpose small doses of calomel ($\frac{1}{8}$ to $\frac{1}{6}$ gr.) at bedtime, and an alkaline saline containing the aperient sulphates on rising, and an hour before midday and evening meals, should be given for a fortnight, and afterwards the calomel or a blue pill may be taken on one or two nights a week, followed the next morning by the saline.

(4) It is of great importance to stimulate the skin and thereby the adrenal-thyroid-sympathetic system, by outdoor exercise in very light clothing, alternate hot and cold baths or douches, and by real or artificial heliotherapy.

(5) In some cases thyroid gland in suitable doses by mouth is of great value, and in very nervous, worrying patients, who sleep badly, a mixture containing bromide and sal volatile should be given thrice daily for a while.

(6) Local treatment of the pruriginous areas is of secondary importance, but the most effective measures are the X-rays, given in fractional doses at suitable intervals, and the application of crude tar, either in a paste, or as a paint, pure or diluted with 1 to 3 parts of acetone-collodion. In mild cases a clean paste, containing the ether-soluble fraction of crude tar, may be substituted. It cannot, however, be too strongly insisted that local treatment alone is only palliative, and it is better to avoid employing radiotherapy except when only a few lichenified patches are present.

(7) Lastly may be considered the various methods of so-called desensitisation. Autohæmotherapy is sometimes helpful, from 3 to 15 c.c. of blood being withdrawn from a vein and injected just before clotting commences into the gluteal muscles. Intravenous or intramuscular injections of a carefully-prepared solution of peptone, given at intervals of from three to seven days in increasing doses, may be successful. In some cases good results have been obtained by hypodermic injections of a stock or autogenous mixed bacterial vaccine prepared according to Danysz' method from intestinal bacteria, or by the deliberate production of protein-shock by means of intravenous injections of *B. coli* or typhoid-paratyphoid vaccine, or of solutions of various vegetable proteins. The writer, however, has found that weekly injections of an autogenous preparation of the substance P. of Oriel, beginning with very minute doses, e.g. 0.1 c.c. of a one-in-one-million dilution, provide the most effective method of desensitisation, and this has been confirmed by others. The dosage, however, must be carefully controlled in order to avoid unpleasant reactions. —

PRURIGO NODULARIS (Hyde) (See Plate 61, D)

(*Lichen obtusus corneus. Urticaria perstans verrucosa*)

This condition, concerning which some confusion still exists, is characterised by the presence of large discrete papules, scattered irregularly, sometimes in groups, chiefly on the limbs, but also on the trunk and occasionally on the face. These papules are hemispherical, hard to the touch, and may attain the size of a nut. Their surface, usually excoriated and covered with blood-crusts, becomes

warty from hyperkeratosis, and irregular. Each is usually surrounded by a halo of pigmentation, and sometimes by a small area of lichenification. In cases in which the itching is very severe, the papules may become surmounted by bullæ, doubtless caused by vigorous scratching. The lesions may disappear, leaving a depigmented macule, bordered by the zone of hyperchromia. Apart from the papules, the skin is usually normal, but may be excoriated, and areas of circumscribed lichenification may be present independently of the papules. The itching, entirely absent in one recorded case, is usually intense, paroxysmal, and chiefly nocturnal, but periods of relative freedom occur, for example when the patient is on holiday.

Ætiology. Like other forms of prurigo, the condition is doubtless allergic in nature, but the nature and origin of the antigen are unknown. It is commoner in women than in men, and, as with other allergic symptoms, psychical influences, such as worry, grief, or shock, are of importance. The duration may be said to be indefinite, as treatment up to the present is admittedly of little avail.

Diagnosis. This presents little or no difficulty as a rule, but the eruption must be distinguished from *hypertrophic lichen planus*, in which the lesions are usually larger and flatter, and often accompanied by the ordinary papules elsewhere or by involvement of the buccal mucosa, and from the condition which may be labelled *lichen obtusus vulgaris*, and is merely a hypertrophic or giant form of lichenification (circumscribed prurigo). The eruption sometimes termed *lichen obtusus corneus* is identical with prurigo nodularis. There are thus three entirely distinct conditions, which are frequently confused: (1) The hypertrophic form of lichen planus, situated as a rule on the legs below the knee, particularly on varicose legs. (2) Lichen obtusus vulgaris, or the hypertrophic form of circumscribed prurigo, also usually seen on the legs, but occurring as well on the thighs, genitals, buttocks, and in the groins. This condition is commonly localised to one or two areas, and the horny papules are closely set on a plaque of lichenification. (3) Prurigo nodularis or lichen obtusus corneus, in which the papules are discrete, and disseminated irregularly, but more or less bilaterally symmetrically on the limbs.

Morbid Anatomy Civatte has confirmed histologically the distinction between lichen obtusus vulgaris and prurigo nodularis. In the former the microscopical appearances are solely those of lichenification. In the latter these are also seen, but they are superadded to a lesion situated deeply in the dermis, which is the essential part of the papule of prurigo nodularis. This lesion consists of a dense infiltration of various types of cells, histiocytes, polymorphonuclear leucocytes, eosinophiles, plasma cells, and mast-cells. Giant cells may also be found.

Treatment. This is usually very unsatisfactory. The application of X-rays to the lesions may give relief from itching for some time and cause them to disappear, but relapse is the rule. A long holiday may result in an entire cessation of the itching with effacement of the papules. Covering the affected parts with an occlusive dressing, such as Unna's paste, may also cause their disappearance.

SUMMER PRURIGO

Under this term, first employed by Hutchinson in 1879, are included conditions that are certainly distinct from one another both clinically and ætiologically. Tentatively one may classify them as follows: (1) *The Juvenile Group*. This includes (a) the severe bullous eruption *Hydroa vaccinoforme*, which is usually associated with hæmatoporphyria congenita, and can hardly be described as prurigo, (b) the mild papular type to which Hutchinson first applied the name "summer prurigo," and (c) the more severe variety of this, in which vesicles and bullæ, as well as papules, occur, and which clinically appears to be intermediate between the first two. (2) *The Adult Group*. This includes the cases of light-

sensitisation, in which susceptibility to light develops for the first time in adult life. In these patients the reaction of the skin to light is usually eczematous in character, indicating *epidermal* sensitiveness, and lichenification of the affected areas results from constant rubbing and scratching; the reaction may, however, be mixed, urticated papules being mingled with a diffuse eczematous dermatitis. More rarely, a simple urticaria (*urticaria solaris*)—i.e., a purely dermal reaction—may be the response to exposure to light. All these varieties of eruption have this in common, that they occur only, or are most intense, in summer, and that they are provoked chiefly by exposure of the skin to light; heat in some cases would also seem to be a predisposing factor. The differences in their clinical characteristics depend no doubt partly on the particular sensitising substance responsible, and partly upon the tissue sensitised, whether dermal, epidermal, or both.

Hydroa Vaccinoforme (Bazin). This rare, congenital, and sometimes familial eruption usually manifests itself in the first year of life after exposure of the skin to sunlight. It consists of lesions beginning as erythematous papules, papulo-vesicles, or directly as vesicles and bullæ, which may be hæmorrhagic or become pustular. They are umbilicated, and dry up to form brownish crusts, beneath which the centre of the lesion is found to be necrotic. On separation of the crust there is seen an ulcer, which eventually heals, leaving a varioliform scar. The eruption occurs on parts exposed to light, and the scarring may cause considerable destruction of the ears, alæ nasi, and fingers. Fresh outbreaks occur every summer, the eruption subsiding to a great extent in winter; after puberty the attacks may cease.

Ætiology. The great interest of this condition is its association with the very rare inborn error of metabolism, hæmatoporphyrinuria congenita. Examination of the urine and fæces shows the pigments described by Fischer—uro-porphyrin in the urine, sterco- or copro-porphyrin in the fæces. The teeth may be coloured pink, and on transillumination, the bones are seen to be darker than normal from the presence in them of the porphyrin pigment. The blood changes indicate great activity of the bone-marrow, and the spleen and liver may be enlarged. It is the shortest ultra-violet rays, those with a wavelength of between 400 and 300 $\mu\mu$, that provoke the eruption. Presumably in these cases the porphyrins are the agents that sensitise the skin to light, for the injection of porphyrin experimentally into a normal person has been shown to have this effect. In cases of hydroa vaccinoforme without hæmatoporphyrinuria, it appears likely that porphyrins may be present in the stools. A similar eruption may occur in sulphonal poisoning, in which there is also hæmatoporphyrinuria.

Pathological Anatomy. The primary change appears to be an enormous dilatation of the blood vessels in the corium, with serous and cellular exudation, which destroys the rete Malpighii and forms a bulla beneath the horny layer. Necrosis of the corium takes place owing to hæmorrhage from and thrombosis of the vessels.

Treatment. As hæmatoporphyrinuria congenita is an inborn anomaly of metabolism, no treatment, apart from the protection of the skin from light, is of any avail. Quinine possesses the property of shutting off the ultra-violet rays, and may be applied as an ointment (R. Quininæ (alkaloid) 5·0, Acid. Oleic. 20·0, Acid Stearic. 100·0, Pot. Hydrox. 5·0, Aq. dest. 400·0), to exposed parts. After applying this, a dusting powder, e.g., R. Quin. Sulph. 1·0, Talc. 15·0, suitably tinted, may be dusted on. More effective is a lotion containing tannic acid: e.g. R. Acidi Tannici 10·0, Spt. vini meth. ind. 25·0, Aq. dest. ad 100·0.—

Summer Prurigo (Hutchinson type). (*Hydroa æstivale of mild type (Colcott Fox). Dermatitis recurrens æstivalis (Radcliffe Crocker).*) These mild cases of "summer eruption" are met with in children and adolescents, and their ætiological relationship to hydroa vaccinoforme on the one hand, and to the adult type of light-sensitisation on the other, requires elucidation. The eruption

consists for the most part of discrete papules, resembling those of papular urticaria, pale and almost the colour of normal skin when not scratched. In mild cases these may be the only lesions, but in others there are papules surmounted by vesicles, or vesicles and even bullæ, as in the case described by Adamson (49), may appear *de novo* on exposure to bright light. The degree of itching, and consequently the secondary results of scratching, vary in different cases, and the lesions may or may not be followed by scarring. The eruption is situated chiefly on exposed parts, particularly the face and the extensor surfaces of the arms and hands.

Ætiology. In some of these cases, especially when actual bullæ are formed, it is probable that porphyrins, due to an inborn metabolic error, are the sensitising agents to light. In the urine the porphyrins fluoresce strongly with ultra-violet light, and can by this means be more readily detected than by the spectroscope.

In other cases there are no porphyrins, and the sensitising substance is unknown.

Treatment. In the cases in which porphyrins are apparently the sensitising substances no treatment, apart from protection from light, is of avail. In others some method of desensitisation should be tried, such as auto-hæmotherapy, and injections of peptone or of the substance P. of Oriel. The last has proved effective in some cases.

Light-sensitiveness of the Adult Type. This is a well-defined clinical entity, distinct from hydroa vacciniforme and from the milder forms of summer prurigo occurring in children. Females are affected more commonly than males, the converse being the case in hydroa vacciniforme. The history usually obtained is that after exposure to strong sunlight, particularly at the seaside, the patient developed an acute dermatitis of uncovered parts with severe irritation, and that subsequently further exposure even to light of moderate intensity caused a recurrence of the symptoms to a greater or less extent. The cases differ according to the degree of their sensitiveness. In some the irritation and the eruption are only provoked by strong sunlight, in others the susceptibility may be extreme, so that the symptoms persist even in winter.

Symptoms. The clinical features of what may be called the adult type of light-sensitiveness are so characteristic that the condition may be diagnosed at a glance. The patient's complexion, even when no active eruption is present, has a sallow, earthy tint, and the vermilion border of the lips is of a characteristic bluish-grey colour. In a case of moderate or great severity, the skin of the face, neck and other exposed parts is definitely thickened, and the natural lines are accentuated, the changes being doubtless partly due, as in ordinary lichenification, to the incessant rubbing and scratching which the intense irritation provokes. The appearances are, in fact, very similar to those seen in the generalised prurigo of allergic origin. The actual eruption, which appears on uncovered parts, when the patient is exposed to light of a certain intensity, is in the early stage an erythema, with a varying degree of serous exudation, the affected areas of skin being bright red and somewhat cedematous. Eczematisation, which is always an indication of epidermal sensitisation, then supervenes, and in an acute attack, numerous, close-set eczematous papules and vesicles arise on the preceding erythematous base. The eyelids are often swollen, as in an eczematous dermatitis produced by chemical or other irritants. Not infrequently urticated papules are mingled with the eczematous lesions, and in rare cases the response to light is a purely urticarial one, there being no eczematisation.

The acute outbreaks are seen most commonly in early spring, and occasionally, after their subsidence, the patients may suffer little inconvenience throughout the summer, except on exposure to strong sunlight. More commonly, however, a chronic eczematisation of the face, neck and the backs of the hands and wrists succeeds the acute phase of the eruption, and the patient experiences paroxysms of intense irritation, which may seriously interfere with sleep. On the nose, malar regions and chin, serous exudation from the eczematous vesicles constantly takes

place, drying up to form yellowish crusts. The skin becomes harsh and thickened from the chronic inflammation, and gradually lichenification results owing to constant rubbing and scratching. On the neck and backs of the hands discrete lichenified papules, similar to those seen in the juvenile cases, are often present. In the more severe cases irritation, with eczematization and lichenification, may occur on parts of the body other than those exposed to light, and in a small proportion of patients, who have suffered from Besnier's prurigo from childhood, light-sensitiveness may develop in adult life.

It will be observed that the clinical features of the eruption in these adult cases differ materially from those that characterise the juvenile form of light-sensitization. In the latter the lesions consist of discrete papules, papulovesicles and bullæ, which dry up to form crusts, and frequently leave pitted scars. In the former the cutaneous reaction is more superficial and of an eczematous nature, and even in the most severe cases scarring, apart from secondary pyogenic infection, is never seen. It would seem that the early inflammatory changes in hydroa vacciniforme are primarily dermic, whereas in the adult form the reaction is, as has been said, more superficial, and due to epidermal sensitization.

Ætiology. The results of investigations (50) carried out in these cases may be summarised as follows:—(1) There is no definite evidence that the sensitiveness to light is dependent upon a porphyrin. (2) In a considerable proportion of cases there is either achlorhydria or marked hypochlorhydria (80 per cent. of cases). This tendency is also found in Besnier's prurigo, and may be an important factor. In neither condition, however, is it by any means constant. (3) *The Fæces.* An abnormal intestinal flora has almost invariably been found, with evidence of excessive putrefaction. Of particular importance probably is the presence of non- or late-lactose fermenting coliform organisms of various types. (4) *The Urine.* Very marked excess of indican or uroscopine is practically constant. In addition a definite excess of urobilin may be found, and specimens taken at intervals throughout the twenty-four hours may give findings similar to those described in allergic states. (5) *The Blood.* The amino-acid content is usually higher than normal. The Van den Bergh test has given a positive indirect reaction in several cases examined. (6) On X-ray examination of the gastro-intestinal tract after a barium meal, visceroptosis, with delay in the cæcum and some part of the colon, was almost constantly found.

From these data, and from the results of treatment based upon them, it may reasonably be inferred that the substance which sensitises the skin to light is formed in the intestine, escapes fixation and destruction in the liver, and thus reaches the systemic circulation. The nature of the substance is unknown. It may be a product of the action of putrefying bacteria upon incompletely-digested protein, or, as some experiments of Knott would suggest, a soluble toxin elaborated by abnormal coliform organisms of the non-lactose fermenting type.

Treatment. From observations on a large number of cases, the only line of treatment, apart from protection of the areas of skin exposed to light, that until recently has given any permanent relief, has consisted of measures designed to inhibit the growth of putrefactive bacteria in the intestine, and to encourage that of fermentative organisms, such as the *B. Acidophilus*. Cases of slight or moderate severity have been successfully treated as follows: (1) *Diet.* A practically vegetarian dietary has been prescribed, consisting chiefly of all kinds of vegetables and fruits, cooked and raw, crisp cereal foods, butter, plain cheese, eggs in moderation, and a liberal supply of glucose, lactose, or lactodextrin. (2) An initial course of high-colon lavage, followed by non-irritating laxatives when necessary. (3) In cases of hypo- or a-chlorhydria the administration of hydrochloric acid and pepsin, in order to favour rapid and complete digestion of protein. (4) Feeding with *B. Acidophilus* milk or cultures, and lactose. In addition, definite benefit would seem to have resulted from injections of a vaccine of abnormal coliform organisms obtained from the stools, or from the oral admini-

stration on an empty stomach of an antiviral prepared from cultures of such organisms. *Locally.* Considerable protection from light can be obtained by the wearing of reddish veils, and by the application to exposed parts of a cream and powder containing quinine, as advised for hydroa vacciniforme.

PRURIGO HIEMALIS

(*Winter Prurigo*)

This variety of prurigo occurs in autumn and winter, disappearing with the approach of warm weather. The attacks of itching are usually provoked when the skin is exposed by undressing or on rising from bed. The itching is usually most intense on the inner surfaces of the thighs, on the legs below the knees, on the extensor surfaces of the forearms and around the joints. Lichenification and follicular excoriation may result from scratching.

Ætiology. Exposure to cold is the principal provoking factor. Unnatural dryness of the skin, which is intensified by cold weather, is often noted, as in senile pruritus, and the itching then occurs chiefly where the skin is naturally driest, namely on the extensor surfaces of the limbs.

Treatment. In patients with dry skins, the avoidance of alkaline soaps and too frequent hot baths, and the application of an emollient antipruritic ointment night and morning may be successful. Stimulation of the skin by alternate hot and cold douches, and by vigorous outdoor exercise in light clothing, or a course of ultra-violet baths is indicated in resistant cases. Sometimes there are signs of hypothyroidism, and thyroid medication will then improve the texture of the skin and diminish its sensitiveness to cold.

DERMATITIS HERPETIFORMIS

(*Duhring's Disease. Hydroa Herpetiformis*)

Duhring, who introduced this term, gave the following definition of the disorder to which he applied it: "An inflammatory, superficially seated, multiform herpetiform eruption, characterised mainly by erythematous, vesicular, pustular, and bullous lesions, occurring usually in varied combinations, accompanied by burning and itching, pursuing usually a chronic course with a tendency to relapse and recur." The eruption is not a common one, but mild forms of it often remain unrecognised, and it would appear to be on the increase in this country. Duhring rightly emphasised its polymorphic character, and this accounts for the difficulty in diagnosis experienced by those without special knowledge.

The different lesions composing the fully-developed eruption are as follows: (1) Erythematous plaques, usually urticated, circular or irregular and gyrate in outline, and varying greatly in size. (2) Urticarial wheals, or urticated papules resembling those of simple prurigo. (3) Vesicles, or more rarely bullæ, giving rise to the herpetiform appearance. They commonly arise on the erythematous patches, but may form independently of them. Their contents are usually clear at first, but may rapidly become purulent.

To these primary lesions are superadded those produced by scratching, namely erosions, which become covered by blood-stained crusts, and linear scratch-marks, and the skin becomes pigmented. The pigmentation is diffuse on the areas most affected, but occurs also as brown macules, surrounding the marks or superficial scars left by the vesicular or papular lesions. During a period of quiescence it is often possible to establish the diagnosis of dermatitis herpetiformis, even in the absence of active symptoms, owing to the distribution and characteristic grouping of the pigmented patches. The sites of election of the eruption are the shoulders, the upper arms near the axillæ, the lower part of the

back and upper portions of the buttocks, the chest, the forearms and the legs below the knees. The buccal mucous membrane is involved in about half the cases, the lesions resembling those of erythema multiforme. The face, the scalp, and even the palms and soles may all be affected.

The disease is subject to exacerbations and remissions. During an active stage fresh lesions appear in small numbers daily or every few days, or there may be periodical extensive outbreaks, followed usually by intervals of comparative calm. The variety of the eruption seems to depend to some extent on the individual affected. Thus in some patients the herpetiform type of lesion predominates; in others, urticated papules and vesicles; in others again, bullæ of considerable size are the striking feature; and the degree of pigmentation varies considerably. Rarely the bullous lesions, particularly in the flexures, become vegetating, recalling the appearances of pemphigus vegetans. In children the bullous form is the commonest, and doubtless corresponds to the *hydroa puerorum* of Unna, and there is less pigmentation; it may be difficult to distinguish from bullous papular urticaria. The writer has seen the latter followed in adolescence by typical dermatitis herpetiformis.

The subjective symptoms are more complex than mere itching, hence Brocq's term "*dermatites polymorphes douloureuses*." The patients complain of burning, tingling, or of actual pain, apart from the predominant sensation of itching. Their discomfort increases, as a rule, towards night time, and insomnia is often a serious result. It is considered one of the characteristics of the disease that the state of general health suffers but little, but in severe cases the long-continued irritation and insomnia react considerably upon the patient's mentality, and he becomes nervous, emotional, and even suicidal.

Prognosis. In the majority of cases, although the disease may last for many years, the prognosis is favourable as regards life. In rare instances, however, the eruption may become transformed into a true pemphigus, ultimately of the foliaceous type, with fatal results.

Morbid Anatomy. The erythematous plaques are constituted by vascular dilatation, with œdema chiefly in the papillary layer of the corium. There is perivascular infiltration, consisting largely of eosinophil cells. The larger vesicles and bullæ may be formed by effusion between the entire epidermis and the papillary body, or between the stratum corneum and the rete, or by the confluence of small vesicles in the rete. The serous fluid contains eosinophiles in large numbers, which may later be replaced by polymorphonuclear leucocytes when it becomes purulent. The eosinophilia in the blood varies from 5 to 30 per cent.

Ætiology. It has been suggested (51) that dermatitis herpetiformis is due to "sensitisation of groups of cutaneous nerve-endings to some bacterial protein from the bowel," and this view is in all likelihood substantially correct. That the eruption is due to involvement of certain nerve-elements in the skin is suggested by the sensory symptoms, and the herpetiform character of the lesions; that it is allergic in nature is probable in view of the eosinophilia and the fact that the same biochemical changes in the blood and urine that occur in other allergic conditions have been found by Oriel in dermatitis herpetiformis. The beneficial effect of an anti-putrefactive diet, and investigation of the intestinal flora, suggest that in most cases, at any rate, the antigen, to which the nerve-elements in the skin are sensitised, is derived from the bowel. It is probable, however, that the actual antigen is not the same in all cases, the characteristics of the eruption being dependent on the particular nerve-elements sensitised, rather than on the specificity of the antigen. A curious feature of the disease is that the patients manifest an intolerance of iodide of potassium, and, to a less extent, of bromides, both when applied externally and taken orally. A 50 per cent. ointment of potassium iodide in vaseline, applied to healed areas of dermatitis herpetiformis, provokes an acute reaction, but this is not found in true pemphigus. Sodium iodide, however, has not the same effect.

On the Continent the view is held that dermatitis herpetiformis is a variant of chronic pemphigus, and that both are caused by infection with a filterable virus. While admitting that a typical case of dermatitis herpetiformis may become transformed into an equally typical one of pemphigus, and end fatally, the prognosis of the former as regards life is nearly always as benign as that of the latter is grave. Moreover, it is difficult to believe that herpes gestationis, which is indistinguishable clinically from dermatitis herpetiformis, can be due to a specific infective organism, since its occurrence is directly connected with pregnancy, the termination of which is followed by recovery.

Treatment. Severe cases should be kept for a while completely at rest in bed; this alone may suffice temporarily to clear the eruption. As pointed out by Norman Walker (52), starvation has the same effect, and he records a severe case in which, after preliminary fasting, a lacto-vegetarian diet has kept the patient practically free from symptoms. The same dietetic rules that are recommended for light-sensitisation (*q.v.*) should be enjoined, and for a while, at least, all forms of meat and fish should be excluded. Glucose, or lacto-dextrin, should be given freely, together with acidophilus milk, in order to diminish intestinal putrefaction. An out-of-door life is advisable when possible, and regular exercise in the fresh air must be insisted upon. *Internally.* Arsenic, given in increasing doses, will almost always control the eruption, and may be prescribed as a temporary measure; but it is never curative, often seems to lose its effect after a while, and is dangerous, if persisted with, owing to its toxic action on the liver and its liability to cause epithelioma, several cases of which have been reported in this disease. Quinine in large doses has also been recommended. An initial course of high-colon irrigation is valuable, and the temporary use of small doses of calomel and the aperient sulphates is advisable until a suitable dietary has regulated the bowels. *Locally.* External applications have a purely palliative action, but a sulphur ointment, as advised by Duhring, applied freely for a few days at a time, often gives great relief, *e.g.*, \mathcal{R} . Sulphur. præcip. gr. xxx. Ung. Zinci ad oz.i. Apart from the above measures, some method of desensitisation is usually necessary. Autohæmo- or autoserotherapy is of undoubted value, as also are injections either of a stock fæcal vaccine, prepared according to the method of Danysz, or of an autogenous vaccine, prepared from the abnormal strains of coliform organisms that are usually found in patients with dermatitis herpetiformis. Recently, however, Barber and Oriel have obtained striking results in several cases by injections of the proteose, obtained by the latter from the urine, in suitable dilutions. This method has in the writer's hands proved itself superior to any other form of desensitisation so far employed. As in pemphigus, injections of germanin have been given with benefit in some cases.

DERMATITIS VENENATA AND TOXIC ERUPTIONS

Many forms of dermatitis can be traced to the direct application of poisonous materials or to their internal administration. Such, for instance, in a mild form is the familiar urticaria of the stinging nettle (*Urtica dioica*), and in a much more severe form the eczematous eruption produced by contact with the leaves of the *Primula obconica*, and with the juice of plants of the order *Anacardiaceæ*, to which *Rhus toxicodendron* and the Indian marking-nut belong. Chrysanthemums, daffodils, lilies-of-the-valley, and many other plants may also cause an acute dermatitis in certain persons. The results of the presence of toxins and allied poisons in the blood are seen in the erythematous eruptions of the exanthems, in the occasional eruptions of pyæmia and septicæmia, in eruptions after vaccination and in the erythematous rashes which sometimes follow the injection of diphtherial and other antitoxins. *Uræmic dermatitis* is a toxic form which is occasionally seen in chronic Bright's disease towards the end of the illness. It often begins as papules or larger elevated patches of red inflamed skin, which

ultimately coalesce, so that the whole body may be covered with red thickened skin. Subsequently desquamation takes place, and some cases have a close resemblance to exfoliative dermatitis. Lastly, we have the poisonous effects of certain drugs when given in undue quality, or unduly retained by inadequate elimination by the kidneys, or in cases of idiosyncrasy.

ERUPTIONS CAUSED BY DRUGS INGESTED

The eruptions produced by drugs are erythematous, urticarial, vesicular, bullous, purpuric, or in some other form; the first four varieties are more common, and especially the first—namely, erythema. The following are the most important:

Antipyrin. A red, papular or morbilliform eruption over the greater part of the body, sometimes with itching and subsequent desquamation. Purpura has also been seen, and sometimes characteristic pigmented erythematous patches.

Arsenic. Urticaria, erysipelatoid rash, or small papules. Herpes zoster and herpes simplex are often provoked by the administration of arsenic either orally or by injection. The long-continued use of arsenic has caused a general pigmentation of the skin, and in psoriasis the healed patches sometimes become very deeply stained. *Keratosi*s, or thickening of the horny layer of the epidermis, especially affecting the soles of the feet and palms of the hands, also occurs, and was seen in the accidental poisoning of beer-drinkers by arsenic in 1900.

Borax and Boric Acid. Inflammations of the skin have occasionally followed the internal use of borax, as well as its application to the surface, and to internal cavities. The eruptions are erythematous, and sometimes bullous, or even hæmorrhagic.

Bromides. An acneiform eruption is common as the result of the use of bromides in epilepsy; the pustules are usually discrete, and occur on the face, chest, back, or scalp, and around the hair follicles on the thigh. More extensive lesions occur in exceptional cases in children on the face and limbs; these are large, oval or circular, much-raised patches of deep red colour, covered with a number of pustular points, or the thick scab which follows their rupture. The substance of the patch is soft; it mostly subsides, and the scab is detached, without leaving any scar, but only a rather persistent stain. The lesions often begin some days after the bromide has been stopped, and their appearance is favoured by any disease of the kidneys which hinders elimination of the drug. Arsenic internally is said to promote their cure, and if given with the bromide may prevent their occurrence. Erythematous, papular, and bullous eruptions are also met with (*see* Plate 61, B, p. 922).

Chloral. Erythematous eruptions, diffuse redness or red papules, and occasionally purpura. They occur mostly after long-continued use of the drug.

Copaiba. Erythema, consisting of bright red, roundish or irregular patches, slightly raised above the surface, here and there confluent, somewhat like measles, covering the arms, legs, trunk, and face. Purpura, vesicles, and urticaria are occasionally present. Desquamation may occur after a persistent eruption.

Cubebs seems occasionally to produce a similar rash.

Iodides. The eruptions are erythematous, pustular, vesicular, bullous, nodular, or purpuric. The erythema is papular, and occurs over the trunk, face, and limbs. Pustules are seen like those of the bromide rash, but smaller in size when discrete; and the confluent forms are less common, and tend to be more bullous. Sometimes large bullæ occur, with a very narrow areola around each, and clear serous contents. Like the bromide eruption, it may be delayed for some days after the drug has been stopped, and is more likely to appear if the kidneys are diseased. The addition of arsenic or aromatic spirits of ammonia to an iodide mixture, or taking the dose in half a tumblerful of water, may be tried to prevent its occurrence.

Quinine. Erythematous rashes are most common, either diffuse or papular; an urticarial form is next most frequent; both of these produce severe itching, and erythema may be followed by extensive desquamation. Purpuric, vesicular, and bullous rashes are less often seen.

Other drugs that have more or less frequently caused rashes, mostly of an erythematous or urticarial type, are belladonna, the barbiturates, cannabis indica, potassium chlorate, chloroform (inhalation), cod-liver oil, digitalis, iodoform, mercury, morphia, opium, phenacetin, phosphoric acid, salicylic acid, santonin, strychnia, stramonium, sulphonal, tar, terebene, and turpentine. Erythematous and lichenoid eruptions, and sometimes a severe generalised exfoliative dermatitis, may result from the infection of metallic compounds, such as those of arsenic, mercury, bismuth, and gold.

The **Treatment** should be the withdrawal of the drug and the use of astringent lotions, such as those of subacetate of lead, oxide of zinc, or calamine.

✓ In the eruptions caused by metallic intoxication sodium thiosulphate should be given both by intravenous injection and orally; and calcium gluconate and glucose should also be prescribed.

ERUPTIONS CAUSED BY DRUGS APPLIED EXTERNALLY

Many substances are applied externally in order to cause erythema and vesication for their therapeutic effects, such as cantharides, capsicum, mustard, croton oil, and turpentine. Belladonna, iodine, sulphur, mercury ointments, arnica, chrysarobin, and pyrogalllic acid are also likely to cause irritation if too long applied to sensitive skins.

An important and frequent cause of dermatitis of the face and neck, and sometimes of other parts of the body, is the use of certain lotions and dyes for the hair. Of these the most important is paraphenyldiamine, which is contained in several proprietary hair dyes and is also used to dye furs. It may produce a most violent dermatitis, which usually begins on the face, ears, and neck, and is apt to cause intense irritation and swelling of the eyelids; in severe cases the eruption may spread on to the chest, back, arms, and even to the lower limbs, and there may be fever, a marked leucocytosis with eosinophilia, and sometimes albuminuria. Numerous other substances, many of which are used in various trades and occupations, will in certain individuals provoke a dermatitis. Of these may be mentioned many aniline dyes, salts of chromic and picric acid, formalin, photographic developers, such as metol, alkalies and acids, and antiseptics, such as corrosive sublimate, biniodide, lysol, and iodoform. Perfumes, such as those of lily-of-the-valley and violets, are frequently responsible in women. In these cases of dermatitis from external irritants (*Dermatitis venenata*) there may be an innate susceptibility of the individual affected, or such susceptibility may be acquired from frequent exposure to the irritant in question. A person, once he has become susceptible, is liable to a recurrence of the dermatitis even after exposure to a minute quantity of the toxic substance, although previously he may have freely exposed himself to it without ill effect.

TRAUMATIC AND SOLAR DERMATITIS

Apart from surgical conditions, *traumatic dermatitis* may be recognised in the marks of scratching, such as are seen in pruritus, jaundice, scabies, and phtheiriasis, to which the reader is referred. These effects are in part due to repeated infections by pus organisms.

Another form of traumatic dermatitis is that intentionally produced in order to *feign* disease, an event most common among young women, who may use nitric acid, mustard, cantharides, iodine, or other irritant. The site of the lesion is generally the breast or a limb, at least a part accessible to the right hand; the

lesion is generally redness with or without vesication or pustulation; but it may be continued until ulceration is produced.

Solar dermatitis (formerly called *eczema solare*) is well known to follow unwonted exposure to the rays of the sun as reflected from the cricket field, the river or sea, and especially from Alpine snowfields. There is intense redness and swelling, with formation of vesicles and bullæ, accompanied by itching and smarting pain, and followed by free desquamation and pigmentation. Of analogous origin is the severe and persistent dermatitis which results from prolonged exposure to the *Röntgen rays*.

ECZEMA

A great deal of confusion still exists as to the precise significance of the word *eczema* (ἐκξέω = I boil over), and there are some who would abolish it altogether, and substitute the term *dermatitis*. If, however, we regard *eczema* as a form of reaction of the skin, possessing well-defined clinical and histological features, and not as a disease *sui generis*, the difficulty is solved, and the disputes that have occurred among dermatologists from the time of Willan and Bateman as to what is and what is not *eczema*, now appear trivial, and certainly serve no useful purpose.

Eczema is an inflammatory process involving the epidermis and dermis, and, unlike eruptions such as urticaria or lichen planus, possesses no single characteristic lesion, but consists rather of a number of lesions, which differ in the various stages through which the inflammatory process passes.

Although the evolution of these different stages varies in different cases, it may be traced as follows: The earliest, or *erythematous stage*, is represented by a patch of erythema, the borders of which are usually ill defined, accompanied by a certain amount of œdema of the affected part, and associated with a sense of tension, burning, or itching. Occasionally the inflammatory process progresses no farther, its subsidence being followed by a fine desquamation, after which the skin rapidly regains its normal appearance. Usually, however, a number of small superficial vesicles appear on the erythematous area, and this, the *vesicular stage*, is one of the most characteristic phases of the eczematous process. By confluence of the vesicles actual bullæ may be produced. In situations where the epidermis is naturally thick, as on the palms and soles, the vesicles appear deeply imbedded in the skin, and may dry up without breaking, but as a rule they soon burst, either spontaneously or as the result of scratching, and discharge a clear serous fluid, which is albuminous and stiffens linen, thus giving rise to the *weeping stage*. The fluid, after flowing for a little, dries up into yellowish crusts which adhere to the surface until detached by accident or lifted by discharge underneath (*encrusted stage*). As the inflammation subsides, the eczematous area becomes paler, the discharge ceases, and healing takes place by a regrowth of epidermis. This may occur spontaneously under the crust, which may remain long after recovery is advanced. For some time, however, the formation of the new horny layer is imperfect (*parakeratosis*), so that it remains thin and transparent, and is cast off as large flakes or papery scales (*stage of desquamation*). Eventually under favourable circumstances the skin regains its normal appearance.

As a result of secondary infection of the eczematous surface with pyogenic cocci, the secretion may become purulent, and the crusts formed are then opaque and greenish-yellowish or orange-coloured, as in true impetigo (*impetiginised eczema*).

Lastly, in cases in which the eczematous process becomes chronic, the persistence of the inflammation and constant scratching and rubbing of the parts by the patient lead to thickening of the skin, with hypertrophy of the epidermis

and infiltration of the dermis. This change, known as *lichenification*, has been described under the heading of Prurigo.

Locally, eczema gives rise to itching, smarting, or burning, and in certain positions to pain on movement. The general condition of the patient, even in cases with an extensive eruption, may be but little affected. In acute cases there is often slight fever, and the digestive system may show signs of derangement, such as a coated tongue, foul breath, anorexia, and excessive thirst. In chronic cases the insomnia resulting from the constant itching, which usually reaches its acme of intensity at night-time, may lead to severe mental depression and irritability.

Varieties of Eczema. Although the clinical and histological features of eczematization are essentially the same whatever the cause, one can, nevertheless, recognise certain varieties of eczema, each of which has special characters of its own. Thus it is often possible to say with certainty, not only from the distribution of the eruption, but also from its appearance, whether an eczema in a given case is of internal or external origin. The acute vesicular eczema produced by irritants, such as turpentine, iodine, formalin, paraphenyldiamine and certain plants, can usually without difficulty be distinguished from that due to an antigen absorbed from within, and it is noteworthy that in the latter the accompanying pruritus is far more severe. Only certain well-defined varieties will be described:—

Nummular Eczema. In the writer's opinion this term should be reserved for a variety characterised by the formation of circular plaques, bilaterally symmetrical, and situated most commonly on the backs of the forearms, wrists, hands, thighs and legs. The elementary lesions are papulo-vesicles of considerable size, which may arise singly; the plaques result from the confluence of these, but even on the fully-formed plaque the individual vesicles can usually be distinguished.

It would seem likely that in this variety the antigen responsible must always reach the skin through the blood-stream, for it is inconceivable that an external irritant could produce an isolated vesicle, and the striking bilateral symmetry on the extremities suggests a blood-borne toxin (cp. erythema multiforme, psoriasis). The source and nature of the antigen, however, is not always the same. In one group of cases the primary source is in the skin itself; for example, a chronic infective dermatitis on a varicose leg, or a varicose ulcer, may, usually as a result of some unsuitable local application, give rise to an outbreak of nummular eczema at a distance, *e.g.* on the forearms. Here the antigen—presumably a bacterial toxin or a product of tissue-destruction—is clearly absorbed from the primary focus on the leg, and carried to other parts of the skin through the blood stream. In another group some septic focus other than the skin is the source, *e.g.* the teeth, and in a third group the antigen is apparently either of intestinal origin, or some derivation of protein metabolism (“gouty eczema” of older authors).

Eczema due to Pyogenic Organisms. Unna at one time held the view that eczema was due to infection of the skin with a specific organism—the morococcus—by which term he was probably describing more than one variety of staphylococcus; but Sabouraud, as a result of careful research, insisted that the primary vesicle of eczema was non-microbic. At the present time it is generally admitted that both staphylococci—particularly the *S. aureus*—and streptococci are capable under certain conditions of producing an eczematous reaction in the skin. (a) *Dermatitis Infectiosa Eczematoides.* This staphylococcal condition has already been described. (b) *Streptococcal Dermatitis.* This form of eczematous dermatitis is most commonly seen in folds, around orifices, or in the neighbourhood of infected wounds or septic ulcers. A chronic fissure in the skin is often present, *e.g.* behind the ears, between the toes, in the groins, at the angles of the mouth (*la perlèche*), the nose, eyes, or anus, which acts as a chronic focus

of infection. The affected area is reddened, cedematous, and shiny, and at the margin there is often a sharply-defined scaly edge, or there may be some vesiculation. Many cases of so-called varicose eczema or eczema rubrum are really of this nature, although the milder forms of the former are due to the staphylococcus. It should be remembered that chronic or relapsing lymphangitis, leading sometimes to elephantiasis, may accompany streptococcal infection of the skin.

Infantile Eczema. Various types of eruption, loosely labelled "infantile eczema," but of totally different causation, are met with in young children, and from the therapeutic standpoint it is essential to distinguish between them. Thus eczematization provoked by external irritants, or secondary to pyogenic infection (see above), may occur in infants as well as older children. The intertrigo of Jacquet ("napkin rash"), already described, may be the starting point of an eczematous dermatitis, which may spread widely from the napkin region to other parts. As has been pointed out, such a dermatitis may be due to infection with a monilia, usually the *Oidium albicans*. Apart from these conditions, however, there are two distinct forms of eczema in infants, which more than others merit the term "infantile eczema." One is really an eczematized seborrhœic dermatitis, the other a true eczema in which the antigen is absorbed from within (allergic type). The former occurs in infants who are likely in later life to develop the various symptoms and infections associated with the seborrhœic state. The latter is usually the earliest manifestation of the tendency to sensitisation, which characterises those who throughout life are liable to the various toxic idiopathies (*q.v.*).

In the seborrhœic type the primary condition is infection of the infant's scalp with the pityrosporon, contracted from the scalp of the mother or nurse. The first symptom is the appearance of discrete scaly patches, situated at first around the hair follicles, and later becoming confluent. These cause irritation, so that the child rubs the scalp, and secondary infection with a staphylococcus takes place. The eruption spreads downwards behind and over the ears to the neck, on to the forehead and central parts of the face, and to the back and chest, as in adults; it may also involve the joint flexures. At first it consists of reddened scaly patches, comparable to the seborrhœic dermatitis of later life, but sensitisation of the skin is apt to occur, so that definite eczematization complicates the primary eruption. It should be noted that, whereas all infants must be exposed to infection with the pityrosporon, it is only in a certain proportion—the future seborrhœics—that this organism becomes established at an early age, and causes active symptoms. Excess of carbohydrates and fat in the dietary is a predisposing factor, as in older children and adults with seborrhœic infections.

The other type of infantile eczema is an eczema *de novo*, *i.e.* is not secondary to any pre-existing infection of the skin, and is due to sensitisation of the epidermis to an antigen or antigens absorbed from the alimentary canal. A considerable proportion of these infants are ichthyotics, and a family history of ichthyosis, eczema, Besnier's prurigo, asthma, or hay-fever is common. Vaccination would often appear to be a factor in bringing about sensitisation of the skin. Although this form of infantile eczema may be met with in breast-fed infants, it is commoner in those fed on cow-milk, and its onset may date from weaning. The distribution differs from that of the seborrhœic form. It often begins symmetrically on the cheeks, and on the forehead, the central part of the face being spared. On the limbs it tends to involve the extensor rather than the flexor surfaces. The scalp and trunk may be affected, but usually later than the face and limbs. The skin of the eczematous areas appears and feels thickened and cedematous; at times there is vesiculation and oozing, but often this is slight, occurring only after a bout of rubbing and scratching. The most striking feature is the intensity of the itching, which, as in the prurigos, is paroxysmal and commonly nocturnal. During the daytime the infant may be calm and happy, but towards evening the eczematous parts become reddened and cedematous, and he begins to rub himself

in a frenzy of irritation, until towards morning the paroxysm subsides, and he falls asleep. There is thus the same periodicity that characterises other allergic conditions, such as urticaria, the prurigos, and asthma, and this corresponds to the same cycle of changes in the urine throughout the twenty-four hours that have been described in chronic allergic states (*q.v.*). Retention of chlorides, with wide and rapidly occurring fluctuations of the water-content of the tissues, has been found in eczematous, as compared with non-eczematous, infants, and the periodical exacerbations of the eczema and pruritus correspond to the times at which there is retention of fluid with its accumulation in the skin.

Ætiology. The essential factor in the causation of an eczematous reaction in the skin is sensitisation of the Malpighian cells, and, since these cells may become sensitised to a great variety of irritants, which may reach the skin either by direct external contact, or through the blood-stream by absorption from within, it is clearly impossible to detail all the possible causes of eczema. Even when it is provoked by an external irritant, however, there is obviously some factor or factors which predispose to the occurrence of sensitisation. Certain persons are more liable to develop eczema both from external and internal provoking causes than others, and this liability may apparently be inborn (idiosyncrasy) and often inherited or acquired; in the former case the person is often subject to other manifestations of sensitisation (toxic idiopathies). Bloch tested the healthy skin of 1,130 people with substances that commonly provoke an eczematous reaction, and found that 35 per cent. of those liable to eczema reacted, compared with 5 per cent. of non-eczematous persons. This increased susceptibility of the skin in certain subjects is probably connected, like the other toxic idiopathies, with the autonomic nervous system and the mineral salts, which regulate its sympathetic and parasympathetic portions. There is no evidence that the latter is connected with the skin, the functional integrity of which is probably entirely under sympathetic control. Klauder and Brown (44), from their investigations of the mineral content of the skin of rabbits, have produced evidence that a high calcium-content and low potassium-content are associated with diminished susceptibility to irritants, and the converse with a heightened irritability. Calcium appears to diminish the irritability both of muscle and nerve-tissue to contact with physical and chemical agents; and it decreases the permeability of the cell-membrane, whereas potassium and sodium increase it, making the cell more receptive for water. The essential lesion in eczema is an œdema of the rete and, as has been noted, during the paroxysms of infantile eczema there is water-retention followed by diuresis. It is quite likely, therefore, that a disturbance of the normal equilibrium between the mineral salts, such as those of calcium and potassium in the skin, with its consequent effect on the sympathetic nerve fibres, may be a factor predisposing to the eczematous reaction. The influence, however, of predisposition or idiosyncrasy is only relative, for whereas only a small proportion of persons who handle *Primula obconica* become sensitised to it, it is possible to sensitise every subject tested by using a concentrated extract of the plant (42). Moreover, all those who constantly handle salts of nickel eventually develop nickel-dermatitis. It is clear, therefore, that the tendency to become sensitised is partly dependent on the irritant in question, or on its concentration.

A tentative ætiological classification of eczema may be attempted as follows:—

Eczema due to External Factors. Physical. In certain persons mechanical irritation of the skin by friction, pressure, rubbing and scratching results in local eczematisation; and likewise exposure to great heat, *e.g.* stokers' or blacksmiths' eczema, to extreme cold, particularly cold winds, and to the actinic rays (eczema solare). The œdema of the skin that results from varicose veins ("varicose eczema"), or from renal disease and cardiac failure, predisposes to local eczematisation.

Chemical. A very large number of chemical substances are capable of pro-

voking an acute or chronic eczematous dermatitis when brought into contact with the skin, and many of them are employed in various trades and professions. Thus the constant use of highly alkaline soaps and washing soda is a very frequent cause ("washerwomen's eczema"); exposure to salt and brine may produce "butchers' eczema," to metol "photographers' eczema," to antiseptics (particularly formalin, perchloride and biniodide of mercury, lysol) "surgeons' eczema." Grocers and sweet manufacturers are liable to eczema from handling sugar. Aniline dyes, picric and chromic acids, hair dyes (particularly those containing paraphenyldiamine), hair lotions, mouth washes and tooth pastes, turpentine, sulphur, etc., are also common causes.

It has been shown that with chemical irritants, *e.g.* iodine, formaldehyde, quinine, eczema may be produced in sensitised persons both when they are applied directly to the skin, or are given by mouth or by injection.

In "bakers' eczema" the skin of the parts exposed to the flour may be sensitive to some or all of the proteins contained in wheat, or it may be caused by some chemical used in baking. An important point to remember is that in many instances the skin of certain parts may become susceptible to an irritant, whereas other parts remain immune. Eczema due to these external irritants, as well as that produced by certain plants, has already been referred to under the heading of Toxic Dermatitis. Although in these cases the provoking cause of the dermatitis is an external one, other factors must often be taken into account. There is no doubt that the general constitutional condition in some way influences the liability to occupational eczema, and the development of susceptibility to a given irritant may correspond to the onset of ill-health; dyspepsia, associated with oral sepsis and constipation, would seem in particular to be a predisposing cause, and it is probable that incomplete digestion and assimilation, and inefficient excretion of toxic waste products, render the skin more susceptible to external irritation. In some cases, at any rate, when the general health is improved, immunity to the irritant causing the dermatitis is completely or partially recovered.

The seborrhœic state, which will be referred to later, is another important predisposing factor to the development of eczematization, and its prevalence among our soldiers in France accounted, partly at any rate, for the severity of the secondary dermatitis that so frequently accompanied scabies. Moreover, seborrhœic persons were found to be more susceptible to mustard-gas dermatitis, and they are very liable to eczema after even a moderate use of sulphur ointment for the treatment of scabies.

Lastly, in ichthyosis, and in persons with very dry skins, there is naturally an abnormal tendency to eczema both from exposure to cold wind, and from the use of alkaline soaps, soda, and other chemicals which are fat-solvents.

Eczema of Internal Origin. That eczema may be caused by certain chemical substances, given by injection or taken by mouth, has already been noted, but, apart from this, antigens derived from food-substances, septic foci, and probably from the action of proteolytic bacteria on undigested protein may be responsible. An injection of a foreign serum sometimes excites not only the usual urticarial serum-rash, but also an acute eczema, owing to the epidermal cells having become sensitised to the antigenic substance in the serum. In the same way certain foodstuffs invariably provoke an attack of eczema in some persons, and the same individual may develop urticaria from one food and eczema from another. In children eczema from food-substances is not uncommon, *e.g.* from cow-milk, cereals, such as oats and wheat, cabbage, beans, pork, and beef, and one or more of the other toxic idiopathies are likely to develop as the child grows older.

Apart from food sensitisation, certain cases of eczema, mostly in adults, appear to depend on *focal infection*, and it is probable that in some instances, at any rate, the eczema is a manifestation of bacterial sensitisation. Oral

sepsis particularly is an exciting cause, and numerous cases have now been recorded in which eczema of long standing has disappeared rapidly after removal of infected teeth. The association of *gout* and eczema has probably been much exaggerated, and, although the two conditions may certainly co-exist, it is rare to see a case of true tophaceous gout in a dermatological clinic. Concerning the connection between eczema and *renal disease* little is definitely known apart from that complicating renal œdema, but in uræmia a generalised eczematous and exfoliative dermatitis may arise; in such cases the amount of urea in the blood is always very high and the eruption is of grave significance, death usually occurring within a few days of its appearance. *Glycosuria* may cause a localised eczema around the vulva, or prepuce, due to irritation by the saccharine urine and the growth of infective organisms, such as moniliæ, but, apart from this, eczema is not uncommon in diabetics. *Retention of fluid*, with its accumulation in the skin, is an important factor not only in infantile eczema, but also in eczemas of internal origin met with in later life. It is predisposed to by an excessive consumption of carbohydrates and fats, particularly if large quantities of fluid are also taken. Several observers have emphasised *nervous shock or strain* as a provocative cause of eczema, and in some persons an acute outbreak may follow a severe shock or period of worry, but the association is probably an indirect one. *Intestinal toxæmia*, associated with excessive putrefaction and indicanuria, is apparently responsible for one variety of eczema, the eruption affecting chiefly the parts of the skin exposed to light, namely, the face, ears, neck, and the backs of the hands; it is probable that in these cases some toxin is absorbed from the intestines which sensitises the skin to sunlight (*vide* light-sensitisation).

The term *seborrhæic eczema* is often used as synonymous with seborrhœic dermatitis; the latter is simply a parasitic infection due to the pityrosporon, the *Staphylococcus albus* also growing actively in the lesions, but a true eczematous dermatitis may complicate the primary eruption, due no doubt to the epidermis having become sensitised to the infecting organisms (cp. *dermatitis infectiosa eczematoides*). This eczematized seborrhœic dermatitis represents, as has been said, one variety of infantile eczema, but is also not uncommon in adults. During the war it was a very frequent cause of disability among our soldiers in France, and was often wrongly diagnosed as impetigo.

Morbid Anatomy. The histological changes met with in the skin in eczema vary according to the stage of the disease. In acute eczema there is great dilatation of the capillaries in the papillæ, with œdema and some leucocytic infiltration. The transitional epithelium becomes œdematous, the prickle cells are separated and disintegrated by the serous exudation (*spongiosis*), and thus vesicles are formed. As a result of these changes in the epidermis the process of keratinisation is interfered with. In the more chronic stages there is marked thickening of the interpapillary processes (*acanthosis*), and more and more infiltration of the corium, with connective tissue proliferation; owing to the imperfect keratinisation (*parakeratosis*), scales consisting of clumps of nucleated cells are formed, and periodically shed. In old patches the thickening of the skin may be very great.

Treatment. Since the possible causes of eczematous inflammation of the skin are so numerous, it follows that successful treatment must depend, as a rule, on accurate diagnosis. Thus many patients have been treated for years for "gouty eczema" of the hands and feet when they were really suffering from eczematoid ringworm, and in recent years recurrent attacks of acute eczema, due to the use of certain proprietary hair dyes, have become increasingly common, and have often been regarded as of constitutional origin. It cannot be too strongly insisted upon that in every case of eczema the possibility of an external irritant being responsible should first be considered. The distribution of the eruption and the history of its onset will usually help one in determining this

point, but, although the cause may obviously be an external one, its discovery may be a matter of great difficulty.

Whatever the cause, the local treatment depends on the stage of the inflammatory process. Thus in acute cases with intense hyperæmia, vesiculation, or weeping, astringent lotions repeatedly applied should be used; when the eczematous surface is drying up, a protective paste or cream should be substituted for the lotion, and in the chronic scaly stage ointments may be employed. The following are suitable lotions in the acute stage: (1) *Liq. plumbi subacetat.*, 1 dr.; *Spirit. vini rect.*, 1 oz.; *Aq. dest.*, ad 8 oz., to which may be added aluminium acetate in a strength of from 1 to 3 per cent.; this should be applied on a single layer of lint, which must be kept continually moist. (2) *R Calaminæ præpt.*, Zinc oxide, āā , 2 dr.; *Glycerini*, $1\frac{1}{2}$ dr.; *Spirit. vini rect.*, $1\frac{1}{2}$ oz.; *Aq. calcis.*, ad 8 oz. (3) *Lotio nigra* and *Aq. calcis*, equal parts. (4) *Ichthyol*, 3 per cent. in water. In some cases a calamine liniment is preferable to a lotion, *e.g.* *R Phenolis liq.* \mathfrak{M} xv.; *Zinci oxidi*, *Pulv. amyli*, *Calaminæ præpt.*, āā 1 oz. *Ol. olivæ*, *Aq. calcis*, āā 4 oz.

As a paste the well-known formula of Lassar is invaluable: *R Zinci oxidi*, *Pulv. amyli*, āā , 2 dr.; *Acidi salicylici*, 10 gr.; *Paraffini mollis alb.*, ad 1 oz., this may be modified by omitting the salicylic acid, which sometimes proves irritating, and by adding a little lanoline. This paste, or a zinc cream, *e.g.* *R Zinci oxidi*, $\frac{1}{2}$ oz.; *Ol. olivæ vel amygdalæ dulc.*, $\frac{1}{2}$ oz.; *Adip. lanæ. anhyd.*, 1 dr.; *Aq. calcis*, 3 dr., may be used alone, or as a base for the incorporation of ichthyol, wood or coal tar, sulphur, resorcin and ammoniated mercury, etc. In subacute or chronic cases, in which these stimulating substances are indicated, the tolerance of the skin towards them must be tested gradually by prescribing them at first in small quantities.

In very chronic patches, in which lichenification has occurred, crude coal tar, pyrogallol, eugallol (the monoacetate of pyrogallol), and even chrysarobin may be employed. Crude coal tar may be painted on neat, or incorporated either with the pigmentum caseini B.P.C. or a zinc paste (*e.g.* crude coal tar, 2 parts; zinc oxide, 2 parts; corn starch, 16 parts; petrolatum, 16 parts); it should never be employed when secondary pyogenic infection has occurred. If used neat, the eczematous surface having been first cleansed with soap and water, the tar is applied as a uniform coating and allowed to dry. The applications may be repeated daily for several days if well tolerated. The above crude coal tar paste is usually by far the most effective local application in the allergic form of infantile eczema. Eugallol is a dark liquid containing 33.3 per cent. of acetone, and should be applied once every few days. Chrysarobin is best employed in an ointment, and its effects must be carefully watched.

The X-rays afford one of the most valuable methods of treating these chronic infiltrated patches. Either a full pastille dose may be given and repeated, if necessary, in a month's time, or fractional doses of a third of a pastille at intervals of ten days. In suitable cases rapid relief from itching is obtained by the use of the rays, and resolution of the thickened patches takes place in a few weeks.

The question of washing must always be considered in the management of a case of eczema, whatever be the cause. Soap should never be used in the acute or subacute stages, but in chronic cases a superfatted soap, with or without the addition of tar or ichthyol, is sometimes of value. Water should be avoided altogether in acute cases, but in subacute and chronic eczema sponging or bathing with a 1 per cent. salt solution seldom does harm, and is often beneficial, for, as Whitfield suggests, the irritant effect of plain water probably depends on the fact that it is hypotonic.

GENERAL TREATMENT. The successful treatment of eczema of internal origin depends upon the thorough investigation of the individual case, and the main principles only can be indicated.

Diet. In widespread or acute cases an initial fast for forty-eight hours is advisable, and the food intake should then be restricted to four tumblers of milk per diem, with some fruit, for three days. An anti-retentional dietary, as recommended for urticaria, should then be instituted, and the total fluid intake should not exceed two and a half pints per diem. Alcohol, strong tea and coffee, and very acid fruits should be avoided entirely. In the allergic form of *infantile eczema* cow's milk must not, as a rule, be given. If the child is being breast-fed, it should be ensured that the mother's dietary contains an adequate quantity of calcium and vitamins, and it is advisable to prescribe for her additional calcium and some preparation containing vitamin-concentrates. If breast-feeding is impossible, some proprietary food, such as Almata, made without cow's milk, should be tried, and additional calcium given in the form of Syr. Calcii Lactophosph. B.P. M 30, t.d.s., with a vitamin-concentrate and orange-juice. The change to a solid dietary should be made as soon as possible, and it may be advisable to perform cutaneous tests with certain foods before planning it. Allergic infants are often hypersensitive not only to cow's milk, but also to some cereals and egg. As Czerny insisted, these children, owing to their tendency to water-retention, thrive best on a diet rich in protein with restriction of carbohydrates, fat and fluids. The following, modified according to individual idiosyncrasies, may be recommended :—

Allowed : Freshly cooked lean meat and fish, chicken, liver, kidneys, sweetbread, and brains ; egg-yolk, cottage or other plain cheese ; all kinds of cooked vegetables, mixed salads, cooked and raw fruit (except very acid ones such as grape-fruit, lemons, pineapple, and currants) ; crisp wholemeal toast, Vitaweat, or Ryvita, butter. One tumbler of milk should be given daily, unless the patient is milk-sensitive. Glucose should be substituted for cane-sugar. Salt should be taken very sparingly. The fluid intake should be restricted to three small tumblers of water a day in addition to the milk and fruit. The diet should be supplemented by a small quantity of a mixed vitamin-concentrate and some preparation of calcium, as advised above.

To be avoided : Porridge, cane-sugar, jam, marmalade, sweets, pastries, puddings, cakes, soups, fats (except butter and cheese), egg-white, pork, bacon, sausage, acid fruits.

Internal Medication. Examination of the urine, specimens being taken at different times of the day, often affords valuable indications for internal treatment. If there is hyperacidity, with or without uratic deposit, alkaline diuretics, combined with the aperient sulphates, should be administered in sufficient quantities to render the early morning urine neutral, the dosage being thereafter reduced. If, however, there is hypoacidity with phosphaturia, acids are indicated, and may be given with a little strychnine. Calcium salts are often of great value, and should be given in combination for a while with full doses of vitamin D. In severe or acute cases they may be injected, as advised for urticaria. Even in eczema of external origin, calcium and vitamin D appear to lessen the hypersensitiveness of the skin. If itching is severe and when there is insomnia, sedatives are essential, *e.g.* calcium bromide gr. 5–10, or luminal gr. $\frac{1}{4}$, thrice daily, and, if necessary, a hypnotic at bedtime. In such cases intravenous injections of calcium or strontium bromide in a solution of glucose (*e.g.* Ekzebrol) may be of value.

In old people in whom the skin is abnormally dry and the general nutrition poor, and in ichthyotic persons, remarkable improvement is often derived from the administration of cod-liver oil and thyroid gland. The former may be combined with malt or iron, and the latter should be given at first in small doses, which should be increased according to tolerance. The importance of treating oral sepsis can hardly be exaggerated, for cases of eczema, which have resisted all other measures, sometimes yield rapidly after the removal of teeth with root abscesses, or the treatment of pyorrhœa alveolaris. Lastly, in patients with

physical or nervous exhaustion a complete rest, followed by change of surroundings, should be ordered whenever possible.

Desensitisation. Even in eczema of external origin, one or other of the various methods of desensitisation may be of value. In fact, in cases of occupational dermatitis autohæmo- or autoserotherapy may enable the patient to resume his work without further trouble. As has been said, eczema due to food-sensitisation has been successfully treated by injecting subcutaneously an emulsion of the food in question in gradually increasing doses, but, as a rule, in eczema of internal origin, the exact nature of the antigen is unknown, and some method of non-specific desensitisation must be attempted. There is, however, evidence to show that the *serum* of sensitised subjects contains a substance specific for the individual or for another sensitised to the same antigen, so that autoserotherapy should, perhaps, be regarded as a method of specific desensitisation. Autohæmotherapy, on the other hand, which is not so certain in its effect, is probably comparable to injections of non-specific protein. Apart from these two methods, peptone, given either by intradermal, subcutaneous, intravenous, or intramuscular injections, is often valuable, as also are the proprietary products "Aolan" and "Cibalumin." In eczema the former is best given intradermally in doses of 1 to 3 minims at intervals of three to seven days.

ERYTHEMATO-SQUAMOUS ERUPTIONS

PITYRIASIS ROSEA (*See Plates 62 and 63, B, p. 942*)

Pityriasis rosea (Gibert) is chiefly of importance in that it is so frequently wrongly diagnosed, and yet the eruption is, as a rule, so distinctive that its recognition should rarely be difficult. In probably the majority of cases one or more patches of considerable size precede the generalised outbreak of the eruption by several days, but their appearance may pass unnoticed. These "herald patches," or *plaques primitives*, are larger than the subsequent lesions, and are usually seen on the neck, trunk or proximal parts of the limbs. They are more or less circular, scaly, and have a well-defined border; they are often mistaken for patches of ringworm, or of seborrhœic dermatitis. The generalised eruption appears with comparative suddenness, like that of an eruptive fever, first on the upper thorax, and then successively on the neck, the upper arms, the abdomen and neck, and on the thighs. A few patches may be seen on the forearms, the face, and lower parts of the legs, and occasionally almost the entire skin, even the scalp, may be profusely covered. The lesions begin as small, pink papules, which enlarge by peripheral extension to form the characteristic circular or oval patches. A typical patch consists of an outer, raised pink border, and a central, fawn-coloured portion, which presents a wrinkled appearance; between the two is a fine collarette of scales, the free edges of which lie towards the centre. As each patch enlarges the centre may fade almost completely, so that the appearance of rings is assumed, the rosy tint of the ring contrasting with the slightly yellowish tint of the enclosed area. A very characteristic feature of the fully developed eruption is the way in which the oval patches tend to run obliquely round the chest and flanks, their long axes lying roughly parallel to the direction of the ribs. The outbreak of the disease may be accompanied by slight malaise, with sore throat and mild fever, but usually constitutional disturbance is not present. Itching may be entirely absent, slight, or so severe that the patient cannot sleep. The lymphatic glands may be enlarged, particularly the posterior cervical group.

Ætiology. It is probable that the disease is due to infection with a filterable virus, which is inoculated at one or more points on the skin, and, multiplying there, produces the "herald patches." Then, after an incubation-period of about five to fourteen days, it presumably reaches the blood-stream and causes the generalised eruption. There is convincing evidence that the hypothetical

virus may be conveyed by new underlinen, and this may account for the increased incidence of the eruption in spring and autumn. Cases have been recorded in which a person has become affected after wearing a garment borrowed from another suffering from the disease.

Second attacks are very rare, but occasionally undoubted instances are met with.

Diagnosis. So characteristic is a typical lesion, with its pink border, its collarette of scales, and wrinkled yellowish centre, and so constant the distribution and arrangement of the patches, that the disease can usually be diagnosed at a glance by one familiar with it, and yet errors are often made. It may be confounded in its early stage with *tinea circinata* or with seborrhœic dermatitis (*pityriasis circinata*); in its developed stage with a secondary syphilide, or even psoriasis. *Tinea circinata* yields a fungus on microscopical examination of the scales. Seborrhœic dermatitis consists of greasy, figurate patches, with follicular papules, and occurs chiefly on the mid-line of the chest and back, and often on the scalp and face. *Pityriasis rosea* should never be mistaken for a roseolar syphilide, since the latter is never scaly, and from the papular syphilide it can be easily distinguished, since the papules of syphilis are darker in colour, are markedly infiltrated, are situate on the distal portions of the limbs as well as on the face and scalp, and are accompanied by other signs of syphilitic infection, such as sore throat, mucous patches, and marked generalised adenitis; moreover, a primary sore can usually be discovered. In psoriasis the scales are larger and present the well-known silvery appearance when gently scratched, and the eruption is commonly present on the elbows, knees and scalp.

Treatment. The eruption disappears spontaneously in from three to eight weeks. If irritated, however, by unsuitable applications, such as sulphur or mercury, the duration is lengthened. The patient should take a daily bath, to which two or three tablespoonfuls of Condyl's fluid may well be added, after which the skin should be dusted over with the pulv. acidi salicylici comp. B.P.C., or a weak salicylic ointment may be used. Whitfield recommends the application of the following lotion twice daily: \mathcal{R} Pulv. calamin præp., \mathfrak{Z} ij; Pulv. zinci oxidi, \mathfrak{Z} ij; Sp. vini rect., \mathfrak{Z} j; Liq. picis carb., \mathfrak{Z} jss; Aq. rosæ, ad \mathfrak{Z} viiij. It is doubtful whether internal treatment has any influence on the course of the disease.

PSORIASIS (See Plate 63, A, p. 942)

This disease consists in the formation of raised red patches, covered with thick silvery-white adherent scales. In a great number of instances the lesions appear first on the knee over the patella, ligamentum patellæ and tubercle of the tibia, and on the elbow over the olecranon. It begins with papules, which enlarge into large flat plaques; quite early the papule is seen to be covered with an opaque scale, and with its enlargement in size the scale becomes thicker, especially in the centre, and silvery white in appearance. The scale is rather firmly adherent, and co-extensive with the red plaque, so that the red colour can often only be seen at the edge. If the scale is removed, it leaves a shining, moist-looking, but actually dry, bright red surface, in which examination with a lens will show a number of deeper red points, the hyperæmic papillæ. The patches are at first round or oval, and enlarge to $\frac{1}{2}$ inch, 1 inch, or more in diameter; fresh patches come out near the first or in other parts of the body. If a patch becomes very large, it may heal in the centre, and thus form a ring; coalescence with other rings will produce serpiginous or gyrate figures. The patches may spread sufficiently to cover large areas of the body continuously, so that the original shape of the spot cannot be detected. The old names given to indicate these different stages have little more than a descriptive value, such as *P. punctata*, *P. guttata*, *P. nummularis*, *P. circinata*, *P. gyrata*, *P. diffusa*, *P. universalis*.

Next to the knees and elbows, the adjacent extensor surfaces of the leg and forearm are most commonly affected, and then the thighs, back, loins, chest, and abdomen; and in all regions a very striking symmetry is observed. The scalp and face are usually attacked when the eruption is at all widespread, but the palms and soles are often spared. The nails are not infrequently involved: they become variously altered, opaque, thickened, pitted, furrowed transversely, or immensely thickened and discoloured (Plate 61, F, p. 922).

The amount of scale varies in different instances or in the same case at different times. In *P. rupioides* the scales are heaped into small conical masses, each on its circular base.

The eruption is usually dry, but may become moist in the flexures, or as the result of irritant applications, and in seborrhœic persons the patches tend to be greasy. Itching is variable, but is not, as a rule, severe. Although it is often stated that psoriasis occurs in persons in perfect health, this is seldom or never true.

The disease breaks out spontaneously, often in early childhood, and, even if not treated, subsides after three or four months, to recur again after a quite uncertain interval. Sometimes the recurrence is twice a year ("spring and fall," as it is often expressed), or a period of years may intervene. In other cases a slight amount of eruption persists, and extensions take place from time to time. During recovery pigment stains mark the situation of the patches, especially after the use of arsenic.

Varieties. *Flexural Type.* Although psoriasis tends to involve principally the extensor surfaces of the limbs, the scalp, and umbilical and sacral regions, it is sometimes curiously localised to the flexures and natural folds of the skin, e.g. the internatal cleft, where it may be the cause of "pruritus ani," the groins, the submammary and hypogastric folds, and the retro-auricular spaces. This flexural localisation is usually seen in late middle-age, particularly in obese persons.

Arthropathic Psoriasis. A severe and often very intractable form of the disease is that in which it is associated with multiple arthritis. Clinically, although the general features of the arthritis are those of the usual type of arthritis deformans, involvement of the terminal interphalangeal joints both of the hands and feet is especially common, and a painful inflammatory form of psoriasis of the nails usually accompanies the joint-changes. Intermittent hydrarthrosis of the larger joints is also more frequent than in non-psoriatic arthritis (53).

Complications. (a) *General exfoliative dermatitis* or psoriasis universalis. There is a generalised erythrodermia, *a capite ad calcem*. Except at certain points, e.g. elbows and knees, the characteristic silvery scaliness ceases. The skin remains dry. The hair may fall to a varying extent, and the nails become striated and deformed. There may be an accompanying arthritis. The histological features remain those of ordinary psoriasis, thus differentiating this form of exfoliative dermatitis from others. Some chronic psoriatics are subject to recurrent attacks of this complication. The general condition usually remains good, there being no serious constitutional disturbances. Sometimes the injudicious use of irritating applications, such as chrysarobin or cignolin, may be responsible for the development of this generalisation.

(b) A very rare complication of psoriasis is an exfoliative dermatitis, in which serous oozing and visible *pustule-formation* are present. It occurs in combination with a streptococcal septicæmia. This moist and pustular eruption may during the course of the infection become transformed into a dry generalised exfoliative dermatitis of the usual type.

Ætiology. As Civatte has insisted, a comparison of the histological features of psoriasis and of the psoriasiform type of seborrhœic dermatitis, which may clinically resemble each other very closely, suggests that the lesions of the

former are inflammatory reactions produced in the skin by a blood-borne toxin or micro-organism, while those of the latter are due, as, indeed, is known, to an external microbial infection. An inherited and familial tendency to the disease is undoubted (54), but observers disagree as to its frequency. Few pedigrees have been published, but at a conservative estimate it would seem that it is present in from 30 to 40 per cent. of cases. Instances are not uncommon in which one or other parent of a psoriatic develops the eruption for the first time in late life. Males are more often affected than females. In Europe and North America the ratio is about 3 : 2. Although beginning most commonly at puberty or in adolescence, psoriasis may be seen in infants, and its onset may be delayed until middle or late life. In women it often appears for the first time at the climacteric, when it tends to affect chiefly the natural folds of the skin.

The actual cause of the disease is unknown. It may, as has recently been suggested, be due to infection with a specific virus, the activity of which, like that of the virus of herpes simplex, is dependent upon factors which vary in different cases. On the other hand, it may be a non-specific cutaneous reaction, like eczema, the tendency to which is inborn and often inherited. In the present state of our knowledge we can merely summarise the known clinical facts, particularly as regards the various provoking factors and the association of the disease with other morbid conditions. In a considerable proportion of cases there is an obvious connection between psoriasis and infection of the throat. Particularly is this so when the eruption appears first in childhood, and it may develop acutely like an exanthem after an attack of follicular tonsillitis or scarlet fever. With subsequent attacks of tonsillitis, further exacerbations occur. It would thus appear that acute streptococcal infection may be the initial provoking factor, or may cause a widespread outbreak when the eruption is already present, whereas other infections, *e.g.* pneumonia and typhoid, usually bring about its temporary disappearance. In adults there is sometimes an apparent relationship between focal streptococcal infection in the teeth, nasal sinuses, or elsewhere, and psoriasis. On the other hand, in many cases of the disease investigation may reveal no evidence of it. In psoriasis arthropathica focal streptococcal infection may certainly be the predominant factor in the causation both of the arthritis and the psoriasis, as in a case observed by the writer in which numerous dead teeth were the source. This, however, does not appear to be so in all cases. Apart from arthritis, other rheumatic manifestations, such as fibrositis and neuritis, are often present in psoriasis, so that lumbago and sciatica are common symptoms. The eruption known as keratoderma blenorrhagica, which is seen rarely as a complication of gonorrhœal arthritis, resembles psoriasis very closely both clinically and histologically, and it has been suggested that it is a variety of psoriasis, in which the gonococcal infection is the provoking cause (55). Lastly, the metabolic factor in psoriasis must be considered. In some cases there is found a high urinary acidity with a tendency to heavy uratic deposit, and a marked increase of uric acid in the blood. The patients, many of whom take alcohol to excess, usually complain of considerable itching. Careful dieting, abstention from alcohol, and the administration of alkaline salines bring about striking improvement, or even the complete disappearance of the eruption. Recently it has been suggested (56) that psoriasis, like xanthomatosis, is due to faulty metabolism of fat. By employing Bürger's tolerance test, it is claimed that an increase of about 40 per cent. in the total serum fat is found in psoriatics, and that a reduction of fat in the diet to a minimum is curative. The writer has employed this method of treatment in several cases, with good results in some, and complete failure in others. To sum up, the tendency to develop psoriasis is inherited and familial in a considerable proportion of cases. Whatever the actual cause of the disease—if, indeed, it is of specific causation and not merely a non-specific reaction of the skin, comparable to eczema and urticaria—there is no doubt that it is in some cases unfavourably

influenced by acute or chronic streptococcal infection, particularly tonsillitis, and that arthritis or other rheumatic symptoms are commonly associated with the eruption.

Morbid Anatomy. The most striking histological feature is *parakeratosis*, characterised by the disappearance of the stratum granulosum and incomplete keratinisation, so that the horny cells retain their nuclei, and accumulate in visible scales, which are drier than normal. This parakeratosis is not, of course, peculiar to psoriasis, but is more marked than in any other eruption. The rete Malpighii is hypertrophied between the papillæ (acanthosis), which are elongated; above the papillæ, however, it is thinned, only a few layers of cells separating them from the parakeratotic stratum corneum. The papillæ and papillary body are slightly œdematous, and their vessels are dilated and surrounded by small numbers of cells, chiefly mononuclear leucocytes. It would appear, from Civatte's researches, that the primary lesion in psoriasis is a small intra-epidermal collection of polymorphonuclear leucocytes ("micro-abscess" of Munro-Sabouraud). These come from the papillary vessels, traverse the rete Malpighii, and collect in its upper layers. The formation of these "abscesses" disturbs the normal process of keratinisation, and they and the Malpighian cells, among which they lie, are cast off as masses of parakeratotic cells, which form the scales.

Diagnosis. In most cases it cannot be mistaken. Patches of dry *eczema* may resemble it, but the edges are not so sharp, and the scales are not so thick and silvery. Moreover, if the surface be gently scraped, droplets of serum will be seen oozing from the rete Malpighii. In psoriasis of the scalp the scales are often yellow, and look like crusts of impetigo; but psoriasis spreads beyond the scalp on to the forehead or neck, and there is usually psoriasis of some other parts of the body, which will be distinctive. *Lichen planus* and *pityriasis rubra* must be distinguished by the descriptions given. Patches of *tinea circinata* may look like psoriasis, but their small number, want of symmetry, small scales, and the results of microscopic examination will show their nature. *Lupus erythematosus* is recognised by its position on the face, the greater thickening of the skin, the sebaceous plugs and the scars, and *scaly syphilides* by the small size of the lesion, the slight scaliness, the browner colour, and the concomitant symptoms.

Treatment. From what has been said concerning the ætiology of the disease it is clear that an attempt should be made to determine the probable provoking factors in the individual case. If there is a history of recurrent tonsillitis or of scarlet fever, and the tonsils appear to be infected, their enucleation is advisable, and should be followed by the administration of an autogenous streptococcal vaccine. This procedure is sometimes curative. Other possible foci of infection should be looked for, and dealt with, if present, and an investigation of the intestinal flora for pathogenic organisms is always desirable. In plethoric persons in whom the eruption is apt to be extensive and irritable, and the urine hyperacid and concentrated, with uratic deposit, a restricted dietary, complete abstention from alcoholic drinks, and regular exercise, together with the administration of alkaline salines (e.g. R. Mag. Sulph., gr. 15; Sodii Sulphat., gr. 15; Sodii Bicarb., gr. 25; Pot. Cit., gr. 30; Aq. Menth. Pip., ad. oz. 1; t.d.s., a.c., ex aqua), will usually produce rapid improvement. It may be said that in alcoholics psoriasis is incurable, unless abstention can be enforced. Whitfield has found that, if marked indicanuria is present, the internal administration of creosote may be curative. With regard to diet, no definite rules can be given. In obese persons carbohydrates and fats should be restricted. Some benefit from an almost vegetarian *régime*, and the low fat dietary, advocated by Grütz, is sometimes effective. In severe cases complete rest in bed is advisable, particularly if the patient is suffering from nervous exhaustion.

For acute outbreaks salicin or sodium salicylate are worth a trial, and in chronic cases arsenic—3 to 6 minims of Liq. arsenicalis well diluted thrice daily after meals—may justify its reputation. Thyroid gland, once regarded as almost a

specific, is only of value when symptoms of hypothyroidism are present. Injections of sulphur compounds were at one time popular, and certainly a course of treatment at Uriage, where the natural sulphur water is injected intravenously, and at Harrogate, often gives remarkable results. Injections of Enesol (salicyl-arsenate of mercury), which is so valuable in lichen planus, have been advocated by Sabouraud, and metallic compounds, such as Psorhanol, Sulpharsenol, and Mercolloid, have proved of benefit in some cases. More effective would seem to be gold-compounds, *e.g.* Solganal B. oleosum, with which the writer has recently had some striking results. The method of treatment introduced by Danysz, which consists of injecting bacterial emulsions (killed at 70° C.) prepared from faecal organisms, in increasing doses at short intervals (three to five days), may prove successful, but often fails. Sutton advises injections of a stock *B. coli* vaccine, combined with vigorous local treatment, and in the writer's hands this has proved to be a more reliable method than any other except the use of gold-compounds.

Local Treatment. Although chrysarobin is by far the most active topical application, it is very irritating and must be used with caution. The same may be said of cignolin, which is in vogue as a substitute at the present time. Oil of cade, Stockholm tar and coal-tar are less rapidly effective. A recent method consists of applying a crude coal-tar paste (Pasta Picis Carbonis B.P.C.) at night time, and irradiating the patches the following day with ultra-violet light. A clean application for general use in ambulant cases, in combination with the other methods of treatment already indicated, is R. Liq. Picis Carbonis B. P., dm. 2; Hydrarg. Ammon., gr. 5-10; Pasta Zinci Co. B.P.C., to oz. 1. For the scalp: R. Liq. Picis Carbonis, dm. 2; Hydrarg. Ammon., gr. 15; Acidi Salicylici, gr. 15; Lanolini, dm. 2; Vaseline. Alb., ad oz. 1; this should be well rubbed in at night time, and the scalp shampooed in the morning. For resistant patches fractional doses of X-rays are temporarily of value, but the patient should be warned of the danger of too frequent applications, for many examples of radiodermatitis are seen in chronic psoriatics. In the majority of cases sun-bathing is beneficial and may banish the eruption completely for several months.

Pustular Psoriasis of the Extremities. It has already been remarked that in rare instances psoriasis may become visibly pustular, for example, in association with streptococcal septicaemia. Recently it has been established (57) that a chronic pustular eruption of the palms and soles, which had previously been labelled "acrodermatitis continua of mild type" (58), is really, in many instances at any rate, a localised form of pustular psoriasis. The eruption tends to involve the palms and soles symmetrically, the sites of election being the thenar eminences and the central parts of the soles, but it may occur unilaterally or asymmetrically, and single patches are met with. It is characterised by reddened scaly patches, in which intra-epidermal pustules are constantly being formed: these dry up to form brownish scabs, which are gradually exfoliated. In a patch of some standing the clinical appearances, apart from the pustules, are frankly psoriasiform. Sometimes vesicles with almost clear contents are seen, and outlying pustules may occur singly in a normal area of skin. On incising the horny layer overlying a pustule and evacuating the pus, an intra-epidermal cavity is exposed. Cultivation of the pus almost invariably reveals that it is completely sterile, it being exceptional even for colonies of a *Staphylococcus albus* to appear. This eruption may occur alone without lesions of ordinary psoriasis elsewhere, or it may be associated with such lesions, some of which may also develop occasional pustules. Sometimes in a long-standing case of psoriasis, the characteristic pustular form will suddenly appear on the extremities (Plate 64, A).

Ætiology. Observations by the writer and others have shown that in the causation of this condition a streptococcal focal infection, particularly of the tonsils, is of primary importance, and several cases have been reported in which complete removal of the tonsils, or other infective foci, has been followed by rapid

cure or striking amelioration of the eruption, which is notoriously resistant to other forms of treatment. Although occurring usually in adults, it may be seen in children; it is equally common in the two sexes. It is possible that a similar pustular eruption of the extremities, due to focal sepsis, may be independent of psoriasis (59). When the identity with psoriasis is certain, it would seem that it is the presence of a streptococcal focus of infection that determines the pustular character of the disease.

Morbid Anatomy. The histo-pathological changes are similar to those of ordinary psoriasis. The chief differences are (1) the far denser leucocytic infiltration of the dermis, which, as in ordinary psoriasis, consists chiefly of mononuclears, at the sites of pustule-formation, (2) the greater disintegration of the rete Malpighii owing to the more extensive exocytosis, there being literally abscess-formation, (3) the denser infiltration of the exfoliated parakeratotic mass with leucocytes, as one would expect. It is this that forms the brownish scabs, resulting from the drying-up of the abscess.

It would appear, in fact, that the visible pustules of pustular psoriasis are merely a greatly exaggerated form of the micro-abscesses of Munro-Sabouraud.

Treatment. In the writer's experience successful treatment depends upon the finding of some source of chronic streptococcal infection. In cases in which no definitely localised focus can be discovered, the throat and stools should be examined bacteriologically for pathogenic streptococci, and, if these are found, an autogenous vaccine should be given. Locally an ointment or paste containing either oil of cade or coal-tar should be prescribed. The eruption is usually resistant to the X-rays.

THE ERYTHRODERMIAS

By the term *erythrodermia* is understood a more or less *generalised* inflammation of the skin, characterised by *redness*, *scaliness* and a tendency to *persistence*. The term is an artificial one, for under it are grouped a number of conditions which, although presenting the above clinical characteristics, are *ætiologically* quite distinct. It should be observed that (1) the *redness* is essentially of inflammatory origin, and is usually accompanied either by thickening, or by thinning and retraction of the skin; (2) the *scaliness* is an important feature, and the scales may be small and powdery, or so large that literally sheets of them are exfoliated daily; (3) the eruption tends to involve large areas, and often affects the whole integument; the nails and hair may be shed; (4) the majority of erythrodermias are *chronic*, and the severe forms persist till death.

The classification adopted by Darier is the most convenient; thus we have: (1) *Primary erythrodermias*, which develop on healthy skin; (2) *Erythrodermic dermatoses*, in which, owing to the generalisation of one of the erythemato-squamous eruptions described above, erythrodermia results; (3) *Secondary erythrodermias*, in which erythrodermia is a complication, often fatal, of some preceding eruption; (4) *Congenital erythrodermia*, occurring in the newly-born.

The primary erythrodermias alone require description here, and are classified as follows:

A. *Acute Primary Erythrodermia*. This form includes one clinical entity, namely, *erythema scarlatiniforme recurrens*, and is also a rare form of toxic eruption caused in sensitised persons by the absorption of certain drugs, particularly mercury, quinine, chloral, belladonna, opium and picric acid.

B. *Subacute Primary Erythrodermia*. This is merely a more chronic and serious form of the preceding. It is seen particularly in alcoholics and those with chronic renal disease, may be accompanied by progressive wasting, diarrhoea and fever, and is fatal in a considerable proportion of cases. Salvarsan dermatitis may be included under this heading.

C. *Chronic Primary Erythrodermia*. (1) *Pityriasis rubra*; (2) *Premycotic erythrodermia*; (3) *Leukaemic erythrodermia*.

PITYRIASIS RUBRA

It is clear from what has been said that the clinical syndrome of generalised exfoliative dermatitis may result from various causes, and at one time the term *pityriasis rubra* was employed indiscriminately in all cases of chronic generalised erythrodermia. It is best, however, to confine it to a group of cases in which the erythrodermia is *primary*, i.e. does not supervene on any previous disease of the skin, and *persistent*, and which often end fatally. The cause is entirely unknown, and *post-mortem* examinations have failed to throw any light on the ætiology. Such cases were described by Hebra; and Jadassohn, who collected eighteen, pointed out that a considerable proportion die of tuberculosis. Typical tubercles with giant-cells and tubercle-bacilli were found in sections of the skin of one case. It is probable, however, that the tuberculous infection, if it be present, is co-existent with, and not a cause of, the erythrodermia.

Symptoms. The eruption begins as erythematous areas, with slight scaliness but without infiltration, as a rule, in the joint flexures. It extends and in time involves the skin of the entire body. The scales are small on the face, but larger on the trunk and limbs, detached at the margins, and frequently and abundantly shed, so that the bed is filled with dry, papery flakes, amounting to a pint or two in twenty-four hours. There is no exudation of serum, and the skin feels dry and hot, but in some cases there occur periodically profuse sweats, which leave the patient temporarily exhausted. For a long time the subjective symptoms are usually slight; the patients complain of feeling cold, and shivering fits are common, but the appetite is good, at times excessive, and nutrition is well maintained. Itching may be slight or even absent, but is sometimes intense and paroxysmal, causing insomnia. The temperature is apt to be subnormal, but pyrexial attacks are common towards the end. In time definite infiltration of the skin occurs, so that free movement is difficult, the hair of the scalp becomes thinned, the lanugo hair disappears, and the nails are affected. After the eruption has persisted for several months, secondary sclerosis and atrophy of the skin occur. The epidermis is thinned, and the whole skin feels hard and inelastic, fitting tightly over bony surfaces and joints. Its colour tends to become darker and more livid, and increased pigmentation, particularly in the natural folds, is noticeable. In rare cases the skin takes on a characteristic bluish-brown hue, which is seen in no other condition. Gradually the patient's strength begins to fail, he wastes, his sweats increase, his mental state becomes affected, so that he is childish and is a prey to delusions, albuminuria and diarrhoea may be present, and the secondary infective complications—cellulitis, deep abscesses, bronchitis, hypostatic pneumonia, etc.—provoke a pyrexial response of varying degree. Hæmorrhages into the skin and mucous membranes are often seen terminally, and their occurrence in the suprarenal capsules may be the apparent cause of death.

Pathology. It is remarkable what little evidence there is of organic disease *post-mortem* in many cases of this obscure condition. Jadassohn's experience that death usually occurs from tuberculosis has been mentioned, but no signs of active tuberculosis have been found in some characteristic cases. On section the skin in the early stages shows the appearances of a superficial inflammation with parakeratosis. In later stages there is atrophic change, the papillæ and inter-papillary processes may be obliterated, the pilo-sebaceous follicles and sweat glands have disappeared, and there is cicatricial contraction of the newly-formed connective tissue, with deposit of pigment in the corium.

PREMYCOTIC ERYTHRODERMIA (See Plate 61, C, p. 940)

The various prodromal eruptions that may precede the appearance of the characteristic tumours of mycosis fungoides are mentioned in the descrip-

tion of that disease. One of these is an erythrodermia, beginning as intensely itching red patches, and becoming generalised. The skin is of a vivid red colour (" *homme rouge* "), more livid in the flexures and lower limbs ; there is much less desquamation, and the scales are smaller than in pityriasis rubra, and here and there may be small islets of healthy skin, which appear depressed below the surface of the surrounding inflamed and infiltrated integument. The nails are not usually affected, except that they are worn and shiny from constant scratching. The itching is intense, much more so, as a rule, than in pityriasis rubra. The subcutaneous lymphatic glands are enlarged and easily palpable. Eventually, often after many years, the nodular tumours of mycosis fungoides arise, but in some cases the erythrodermia may spontaneously disappear and later recur, or death may result from cachexia or an intercurrent infection before the appearance of tumours.

The histological appearances of premycotic erythrodermia are characteristic. There is a dense infiltration, composed of lymphoid cells, lying in the papillary zone and sharply limited below ; the papillæ are broadened and elongated ; the interpapillary processes are thinned and often bifid ; the horny layer is thickened and in places parakeratotic ; and here and there lying in the Malpighian layer are seen little nests of lymphocytes, which are pathognomonic of mycosis fungoides.

LEUKÆMIC ERYTHRODERMIA

Leukæmia, like Hodgkin's disease, may be accompanied by various cutaneous manifestations (60). In acute leukæmia, which is usually of the myeloid rather than the lymphoid type, the lesions may be divided into (1) leukæmic tumours ; (2) dermatoses of various kinds. Of the latter purpura is by far the commonest, but erythematous rashes, papules, vesicles, hæmorrhagic bullæ, and erythrodermia may occur. In chronic myeloid leukæmia tumours in the skin are very rare ; cutaneous and subcutaneous hæmorrhages are seen, usually towards the end, and pruritus has been described. In chronic lymphoid leukæmia tumours are not uncommon, and may be present before the occurrence of leucocytosis, although a differential count usually shows a relative lymphocytosis. Apart from tumours, there are other cutaneous manifestations—the *leucemides* of Audry and Germès ; they are polymorphic, and usually accompanied by pruritus. They take the form of *urticaria*, which may be of the papular or vesicular type, *erythemata*, simple or bullous, imitating erythema multiforme or even dermatitis herpetiformis, and *prurigo*, recalling that seen in Hodgkin's disease. It is probable that these various types of eruption, and the erythrodermia to be described, are due to toxins liberated from disintegrated lymphocytes.

Leukæmic erythrodermia is not very rare, and different forms of it have been distinguished. Thus some are relatively acute and febrile, corresponding to the group of subacute primary erythrodermias ; others are essentially chronic, and simulate pityriasis rubra ; others again are partial, and resemble psoriasis. The commonest variety clinically resembles premycotic erythrodermia very closely, but the itching is usually less intense. Sequeira and Panton have described a series of cases under the term *lymphoblastic erythrodermia*, characterised by a moderate leucocytosis, 8,000 to 30,000 per cubic millimetre, with an increase of the small lymphocytes up to about 75 per cent. There seems, however, no reason to separate these cases from leukæmic erythrodermia. In the differential diagnosis between premycotic and leukæmic erythrodermia the following points should be noted : (1) The blood picture ; (2) the histology, that of premycotic erythrodermia being characteristic ; (3) The X-rays have little or no effect on leukæmic erythrodermia, but their action on mycosis fungoides is striking, though temporary.

PITYRIASIS RUBRA PILARIS (See Plate 61, E, p. 940)

This rare disease should, perhaps, be considered with psoriasis, which it closely resembles. The primary lesion is an acuminate, red follicular papule, with a

broken hair in its centre, and surrounded by a horny collar, which dips into the follicle. These papules are seen best on the hairy parts of the limbs, especially on the extensor surface of the forearm and on the dorsal parts of the fingers. Apart from the primary follicular lesions, red, scaly patches, resembling psoriasis, appear on various parts of the body, and they may extend until a generalised erythrodermia results. The palms, soles, and face are particularly affected. The evolution of the disease varies. The onset is usually sudden, and the eruption spreads rapidly until the whole skin is involved. The erythrodermia may remain generalised for several months, and then disappear slowly or rapidly until the skin returns completely to normal; or the greater part of the eruption may clear, but certain areas, usually the palms, soles and face, remain affected sometimes for years. Two or more attacks may occur in the same patient. The general health is but little affected, but there may be slight fever at the onset, and during the erythrodermic stage of the disease. The inflammation and thickening of the skin give rise to a sensation of heat and burning, and there is great discomfort from cracks on the palms and soles, and from the ectropion, which may result from involvement of the face.

Morbid Anatomy. There is hyperkeratosis of the infundibular parts of the follicles, which thus become plugged with cones enclosing the broken or atrophied hairs. In contrast with psoriasis, the stratum granulosum persists and may be hypertrophied. The rete Malpighii may be thinned or slightly thickened. The vessels of the papillæ are congested, and surrounded by cellular infiltration.

Ætiology. An inherited tendency has been observed in several instances. The writer has seen four examples of the disease occurring in mother and child, and several members of a family in more than one generation may be affected (54). This, however, is, of course, also true of psoriasis. The actual cause is unknown. The suggestion that it is of tuberculous origin has little to support it; it is more likely that it is due to an unknown infective organism.

Diagnosis. The follicular lesions must be distinguished from such conditions as lichen spinulosus and the follicular variety of lichen planus. In their absence the resemblance of the red scaly patches to psoriasis is close, particularly as they often occur on the elbows and knees. The early involvement of the palms and soles, however, is a striking feature of pityriasis rubra pilaris. The generalised form of the disease, in which the follicular lesions may be absent, imitates other erythrodermias.

Treatment.—The local treatment is like that of psoriasis, except that chrysarobin should not be employed. Oil of cade is, perhaps, the most effective application. Internally, the administration of arsenic in increasing doses, and of thyroid seem to be of benefit, but the disease often seems to run a definite course without apparently being influenced by any form of treatment. Injections of gold compounds have been of apparent value in some cases.

PAPULAR ERUPTIONS

The term lichen has been long in use to signify any sort of papular eruption, but is now generally restricted to two diseases: one falls in the present group, *lichen ruber planus*, or *lichen planus*; the other is a tuberculide, *lichen scrofulosorum*.

LICHEN PLANUS (See Plate 63, A, p. 942 and 64, B, p. 945)

The elementary lesion of *lichen planus* is a papule, of which there are four varieties:—

(1) *The polygonal papule* is formed in a space between the natural lines of the skin, which constitute its boundaries and determine its shape (cf. lichenification).

(2) *The obtuse papule* is larger, shiny, and translucent in appearance; in its

centre is a minute depression, sometimes with a horny plug, corresponding to the mouth of the sweat-gland, around which it is formed.

(3) *The plane papule*, not so common as the above varieties, is hardly raised above the surrounding skin.

(4) *The follicular acuminate papule*, the least common of all, is characterised by a horny spine, formed by follicular hyperkeratosis. These follicular lesions, when they occur, usually coexist with other papules, but may be found alone, and probably many cases labelled lichen spinulosus are really follicular lichen planus.

In the majority of cases the fully-developed eruption is constituted by the first three varieties of papule, which by confluence form plaques and figures of varied design. The elementary papules are usually pink in colour, dry and firm to the touch, and their surface has a characteristic sheen or burnish. The fully formed papule and the confluent patches tend to develop a lilac hue, which is almost pathognomonic. Still more so are the opalescent white lines or points, known as Wickham's striæ, which tend to form a network on the surface of the adult papules, both when single or coalescent. They are due to the irregular distribution of keratohyalin in the granular layer of the epidermis, and can be rendered more obvious by sponging the surface of the papules with aniline oil or water, in order to increase the transparency of the horny layer. The confluent patches become covered with fine adherent scales; occasionally the hyperkeratosis may be so marked that at first sight the eruption resembles psoriasis.

In cases of some standing there is usually hyperpigmentation, the papules and plaques becoming darkened, and sometimes surrounded by a brownish halo; and the coexistence of lichen planus and vitiligo is not rare. After resolution of the lesions, their former sites are marked by pigmentation, which is most intense on the lower limbs, and is undoubtedly increased by arsenical medication.

The sites of election in lichen planus are the anterior surfaces of the wrists and forearms, the inner surfaces of the thighs just above the knees, and the legs, but the eruption is often generalised and sometimes more profuse on the trunk than on the limbs. On the palms and soles, owing to the thickness of the horny layer, the appearances are deceptive. The papules are hyperkeratotic, and at first sight resemble vesicles: shedding of their horny covering results in a pitted condition comparable to that seen in the punctate keratoderma of Mantoux, in Darier's Disease, and in arsenical keratosis. Sometimes, however, there are red, scaly patches, or even a diffuse keratoderma. Lichen planus, though rare on the face, is not so uncommon on the scalp as is usually thought; it is often mistaken for circumscribed prurigo, or for lichenified seborrhœic dermatitis. It forms dry plateaux with well-defined steep edges, and a careful examination will reveal the lilac tint and the white striæ. Sometimes, however, the patches are atrophic, and the hair is destroyed. This variety is usually associated with a follicular eruption on the body.

The subjective symptoms vary according to the individual affected. The itching may be intense and continuous, driving the patient to distraction; more commonly it is moderate in degree and paroxysmal, particularly, as in the prurigos, at night time; sometimes it is slight or entirely absent. Occasionally patients complain rather of soreness than of itching. Even when the pruritus is severe there may be little or no evidence of scratching, but in some cases lichenification is superimposed upon, and may mask the primary eruption.

Lichen planus not infrequently involves the mucous membranes, particularly that of the mouth, upon which it occurs in about half the cases. It is important to remember that the mucous membranes may be alone involved, or may be affected before the appearance of cutaneous lesions; and in the mouth the eruption often persists long after it has cleared from the skin. On the *oral mucous membrane* the sites of election are the internal surfaces of the cheeks, opposite the junction of the upper and lower teeth. The lesions consist of milky

white spots, often forming a network or rings; the white colour is characteristically tinged with blue, and is more opalescent than that of leucoplakia. There may be superficial erosion, so that deep-red patches, which often cause discomfort, are seen, surrounded by a bluish-white network. On the *tongue* patches of varying size or a similar network occur, and the same bluish-white colour is seen. The lesions may involve the dorsum or the sides. More rarely the eruption is extensive, affecting not only the cheeks and tongue, but also the palate, the lips, both on their vermilion borders and inner surfaces, the gums, and even the tonsils. On the *vulva* the patches are also milky white, but on the glans penis the papules resemble more often those on the skin, and commonly form annular figures. The *anus* and *rectum* may also be affected.

The histological changes of lichen planus of the mucous membranes are exactly comparable to those of the cutaneous lesions. The *diagnosis* is of importance, as buccal lichen planus is often mistaken for leucoplakia, tertiary glossitis, or for mucous patches. The colour of leucoplakia is different, lacking the bluish tint of oral lichen, and being *mat* rather than opalescent; moreover, the surface of the patches appears finely striated. Lupus erythematosus affecting the buccal mucous membrane is not uncommon (about 30 per cent. of cases); it occurs on the free border and inner surface of the lips, usually the lower, and on the cheeks, where it may be confused with lichen planus. The white patches, however have a bright red base with purplish stippling, and there is usually partial atrophy. The tongue and palate may be affected.

Varieties. Lichen planus is usually one of the simplest eruptions to diagnose owing to the clear-cut picture provided by the elementary papules, the white striæ, and the characteristic lesions in the mouth. On the other hand, there are anomalous forms of the disease, which may deceive even the expert for a while. Among the most important varieties may be cited:—

(1) The *annular* form (*lichen annulatus*). The papules tend to group themselves in rings, 6 to 8 mm. in diameter, with a pigmented centre. More rarely a ring may be formed by the peripheral extension, with central involution, of a single papule. This annular variety is common, and the rings are seen chiefly on the wrists and forearms, the flanks, and on the glans penis.

(2) The *gyrate* form (*lichen marginatus seu serpiginosus*), in which the papules extend centrifugally to produce figures comparable to those of erythema annulare centrifugum.

(3) *Lichen striatus* is the name given to the characteristic rows of papules that develop along scratch marks.

(4) *Lichen linearis*. The lesions form long, narrow bands, which may appear to follow the trajectory of a nerve, *e.g.* the small sciatic, internal cutaneous, and ulnar, or may be quite straight, and apparently independent of any nerve distribution. Comparable to these cases are those in which lichen planus develops in a zoniform manner, with a distribution exactly corresponding to that of a herpes zoster.

(5) *Lichen acuminatus*. This is the follicular form of lichen planus already referred to. When the acuminate follicular lesions coexist with plane papules, the variety *lichen planopilaris* is produced. Recent observations indicate that many cases of so-called lichen spinulosus are really the follicular form of lichen planus. Moreover, the association of "lichen spinulosus" with bald, atrophic areas on the scalp has been noted in several instances, and the question arises whether these latter are not atrophic lichen planus, and whether the condition labelled *pseudo-pelade* is not also in some instances atrophic lichen planus confined to the scalp.

(6) *Lichen corneus hypertrophicus, seu lichen verrucosus*. In this variety raised warty plaques are formed, as a rule on the legs, particularly when varicose. They may be discrete, but are usually grouped or even confluent. They are reddish to purplish-brown in colour, and their surface is studded with horny

follicular plugs, or pitted when these have fallen. This hypertrophic form of lichen planus must not be confused with the so-called *lichen obtusus corneus*, which is really prurigo nodularis (*q.v.*).

(7) *Lichen planus atrophicus seu sclerosus* is very rare. The characteristic lesion is an ivory white papule, firm to the touch, and usually neither raised nor depressed. On the surface may be found black, horny plugs, situated in the orifices of the pilosebaceous follicles or sweat-ducts, or the pits that mark their former sites. Histologically there is found a band of sclerosis between the epidermis and the infiltration in the dermis. This atrophic lichen planus is doubtless one form of so-called "white-spot disease," of which the other is guttate morphea.

(8) *Lichen planus bullosus*. This is excessively rare. The bullæ are formed between the epidermis and the papillary layer. In some cases it appears to be due to arsenical medication.

(9) Lastly may be mentioned a variety in which an acute eruption of erythematous more or less oval patches develops chiefly on the trunk, resembling very closely in its early stages *pityriasis rosea*. It is only when the eruption has been present for some days that the characteristic lichen papules appear in the patches.

Ætiology. The cause of lichen planus is unknown. It is almost certain that, as in herpes zoster, the actual lesions are infective in origin, and caused by involvement of certain nerve-fibres. Like herpes zoster, an outbreak of lichen planus may be provoked by injections of the organic arsenical compounds, and by bismuth and gold preparations. In a case of vitiligo observed by the writer, an eruption of lichen planus, *with an exact zosteriform distribution*, appeared during a course of injections of novarsenobillon, and disappeared spontaneously in about three weeks. Moreover, in some cases of so-called linear lichen planus the eruption appears to follow closely the course of a cutaneous nerve, *e.g.* the internal cutaneous and ulnar, the small sciatic, or the inferior gluteal and popliteal nerves; in others the distribution is comparable to that of a segmental nævus. The undoubted therapeutic action of X-rays applied over the spinal column, particularly over the cervico-dorsal and lumbo-sacral regions, is significant, and it is of interest that in some cases this method of treatment may provoke an acute generalised outbreak of the eruption. The favourable effect sometimes observed of lumbar puncture, with the withdrawal of several c.c. of cerebro-spinal fluid, can hardly be explained otherwise than by some obscure action on the nervous system.

The influence of shock, worry, and grief is in some cases apparent, but the eruption may occur in healthy, happy persons, and in young children.

Morbid Anatomy. The inflammatory process in *L. planus* begins round a sweat duct in the upper part of the corium; there is a dense growth of connective tissue cells, which are, according to some, of granulomatous type. This is followed by increase of the cells of the stratum mucosum, and thickening of the horny layer. There is irregular thickening of the eleidine, which causes the appearance of white striæ, above mentioned.

Treatment. In severe, generalised cases, and in patients suffering from nervous exhaustion, complete rest in bed for a few weeks should be enjoined. The oral administration of arsenic in increasing doses has deservedly fallen into disfavour. Mercury in the form of the liq. hydrarg. perchlor. appears more efficacious, and is usually well borne. Much more certain in their effect are injections of the organic arsenical preparations—novarsenobillon, acetylarsan, soamin, etc.—or of arsenical and mercurial compounds, such as Enesol (salicyl-arsenate of mercury). Novarsenobillon may be given intravenously in doses of 0.3 to 0.6 gm. at intervals of from one to three weeks, but it occasionally provokes widespread extension of the eruption with considerable malaise. Enesol is injected intramuscularly in doses of 2 to 5 c.c. at intervals of three to seven days.

The toxic effect of these metallic compounds is apparently lessened by the oral administration of glucose, 2 to 3 ounces per diem in divided doses.

On the Continent irradiation of the spinal column is now much in vogue, either by deep, filtered rays, applied obliquely to act on the nerve-roots (Hufschmidt and Pautrier), or by non-filtered rays in doses of 5H to the cervico-dorsal and lumbo-sacral regions with the idea of affecting the sympathetic (Gouin). Both methods may, like injections of arsenobenzol, cause a temporary acute outbreak of the eruption, and, although strikingly successful in some cases, may fail entirely.

Lumbar puncture, with the withdrawal of 6 to 8 c.c. of cerebro-spinal fluid as Thibierge and Ravaut have pointed out, is of value in generalised cases with intense itching. It usually has an almost immediate effect on the pruritus, and in some cases appears to hasten the disappearance of the eruption. To obtain the desired result, two or more punctures at intervals of a few days may be necessary.

Local Treatment. In patients with an acute widespread eruption soothing antipruritic applications should be employed. A daily tar bath may be taken, and a calamine lotion, containing liq. picis carbonis and phenol, subsequently applied freely. In less acute cases a cream, ointment, or paste containing tar, phenol, and ammoniated mercury are of value. Unna's well-known ointment consists of mercuric chloride 2 to 20 grains, phenol 5 to 20 grains, zinc ointment 1 ounce, the quantity of perchloride and phenol being raised according to the extent and thickening of the patches. For chronic patches a strong tar paint or collodion, or a plaster containing perchloride, phenol, and salicylic acid, relieve the itching and may hasten resolution. Obstinate chronic plaques of hypertrophic lichen planus are best treated by a full pastille dose of X-rays, by the filiform douche, or by repeated freezing with carbon-dioxide snow.

On the buccal mucous membrane the eruption is much more resistant to treatment than on the skin, but it may yield to injections of the organic arsenical compounds, particularly of acetylarsan according to Audry. Radiotherapy applied to the nape of the neck and local treatment with radium have been recommended in resistant cases.

LICHEN NITIDUS

This eruption was first recognised as a clinical entity in 1901. Numerous cases have subsequently been described, and the writer (61) in a review of the literature has confirmed the view that lichen nitidus is but an atypical variety of lichen planus, with special histological features, and the ætiology is the same.

Symptoms. The elementary lesion of lichen nitidus is a minute papule formed by a more or less sharply defined granuloma, which lies, as a rule, just below the epidermis. These papules are not usually larger than the head of a pin, flat, conical or globular in shape, and slightly raised above the surface. Their colour varies in different cases, and is commonly reddish or reddish-yellow. A very characteristic feature is that they often have the glistening appearance implied by the epithet "nitidus," and appear as minute reddish spots shining through a transparent overlying epidermis. Sometimes they look almost like small vesicles, recalling the sago-grain appearance of cheiropompholyx. On pressing with a glass slide, they remain as opalescent points of a darker colour than the surrounding skin, rendered anæmic by the pressure. Sometimes there is a minute depression in the centre of the papule, but this is by no means a constant feature. At the apex of some papules it is possible by scratching to produce a tiny bright scale. There is, as a rule, no connection between these elementary lesions and the pilo-sebaceous follicles.

As has been said, in many cases the eruption consists merely of these papules, which remain discrete and are unaccompanied by any changes in the surrounding skin. In such cases they usually have a strictly limited distribution, occurring chiefly on the penis in men, the lower abdomen, groins, and inner surfaces of the

thighs, and on the flexor surfaces of the wrists and forearms and backs of the elbows.

In other cases, however, the eruption becomes widespread and loses its primary papular appearance in certain regions. In such a case one can probably always find, by careful examination of the whole body, certain areas where the elementary papules are discrete and typical of the simple form of the disease. In generalised cases they are present on the lower abdomen, groins and thighs, but elsewhere the eruption consists of diffuse pityriasiform or psoriasiform sheets, which are, when once recognised, very characteristic in appearance. Their colour varies in different patients and in different situations, being either reddish-yellow, brownish, or reddish-violet. In the flexures the reddish tint predominates, while on the extensor surfaces of the limbs the patches are often yellowish-brown, or hardly darker than the surrounding skin.

The distribution of these diffuse sheets of the eruption may be widespread, but they are particularly likely to involve the joint flexures, such as the antecubital and popliteal spaces. The anterior surfaces of the wrists and lower part of the forearms, the extensor surfaces of the knees and elbows, the folds of the neck, the submammary region in women, the groins and thighs, the palms and soles and dorsal surfaces of the hands and feet may all be affected. On the knees and elbows the patches are triangular in shape, the apex of the triangle pointing downwards. Here they look not unlike patches of lichenification, but the accentuation of the natural furrows of the skin is absent or but little marked. They differ from psoriasis in that their colour is brownish-yellow, on scratching they become only slightly scaly, and the scales have not the characteristic silvery appearance of psoriasis. In the joint flexures they may also resemble somewhat areas of lichenification, but their colour is usually of a lighter red or reddish-yellow, there is no accentuation of the natural lines of the skin, and there is less thickening.

At the periphery of the diffuse patches one can sometimes see outlying discrete elementary papules, and they may also often be discerned, even in the central parts, by putting the skin on the stretch and thus rendering it anæmic.

Pathological Anatomy. The microscopical features of lichen nitidus are characteristic. A single papule consists of a sharply circumscribed granulomatous infiltration, lying as a rule immediately below the epidermis, which is thinned above it and sometimes actually invaded by it, and consisting of epithelioid cells, small round cells of the mononuclear type, with occasional giant cells, embedded in a stroma of oedematous connective tissue. There may be a definite gap between the epithelium and the area of infiltration, but, as a rule, they merge into one another, and one finds degenerated epithelial cells lying actually in the infiltrate. The epidermis tends to send down acanthotic prolongations on either side of the infiltrate, which may be even completely surrounded by them, a feature that is considered pathognomonic. The vessels going to the little granulomatous nodule have thickened walls, the lumen in some cases being completely obliterated, and around them is a well-defined cellular infiltration. The connective and elastic tissue may be completely destroyed in the centre of the nodules, which usually bear no relationship to the follicles or sweat-ducts. A section taken from a confluent patch will show several such nodules of different sizes and in various stages of evolution.

Treatment. Since recognising the probable identity of lichen nitidus and lichen planus, the writer has treated two extensive cases with intravenous injections of novarsenobillon with satisfactory results. Probably the alternative methods of treatment suggested for lichen planus would be equally efficacious.

PARAPSORIASIS

Under this term, first proposed by Brocq in 1902, has been included a group of eruptions characterised by erythemato-squamous patches of varying size and

distribution, which are very resistant to treatment and the causation of which is unknown. In 1890 Unna, Santi, and Pollitzer described them as *parakeratosis variegata*, and aptly compared them to "a mixture of psoriasis, lichen planus, eczema, and pityriasis rosea." In 1901 Fox and Macleod included under the term "Resistant maculo-papular scaly erythrodermias" the *erythrodermie pityriasique en plaques desséminées* of Brocq; the dermatitis psoriasiformis nodularis of Jadassohn; the pityriasis lichenoides chronica of Juliusberg; the lichenoid psoriasiform exanthem of Neisser; and parakeratosis variegata. Brocq divided his parapsoriasis into *P. en gouttes*, *P. lichénoïde*, and *P. en plaques*, but although this division is convenient, it is very doubtful whether the three types are ætiologically connected, and confusion still exists even as regards their clinical classification.

Parapsoriasis guttata. (*P. en gouttes. Pityriasis lichenoides chronica.*) The eruption involves chiefly the trunk and upper segments of the limbs. It consists of small superficial papules, circular or oval, and varying in colour from pink to reddish-brown or fawn. They are covered by a characteristic mica-like scale, which may give to the lesions a false impression of superficial atrophy. At first sight the eruption might be mistaken for *Pityriasis rosea*, a guttate psoriasis, or a papulo-squamous syphilide in course of resolution, but the adherent scales are pathognomonic. Despite the term pityriasis lichenoides chronica, it has recently been recognised that the disease may have an acute onset and develop rapidly, like *Pityriasis rosea*; as in the latter, a "herald-patch" has been observed in some cases. Moreover, it is now known that *pityriasis lichenoides et varioliformis acuta* (Habermann. Mucha.), which was comparatively common in this country a few years ago, is merely a variety. In this, apart from the lesions already described, vesicles, which tend to become hæmorrhagic or pustular, arise, undergo necrosis, and leave varioliform scars. It may be confused with chicken-pox, particularly as the onset is abrupt and there may be some constitutional disturbance with adenopathy. The acute form of the disease, with or without varicelliform lesions, tends to run a definite course, but its duration, unlike that of *Pityriasis rosea*, is indefinite, varying from some weeks to several months, and recurrences have been reported. In the varicelliform variety the necrotic vesicular lesions may cease to form after a while, whereas the others may persist for a long time.

Ætiology. The disease is seen as a rule in adolescents and young adults, but may occur in children. The acute variety must be due, like *Pityriasis rosea*, to an unknown infective organism, probably a filterable virus, and this is doubtless also true of the chronic form, since there are no valid reasons for separating the two. It is logical, in fact, to regard the condition as a specific disease of infective origin, and as being entirely distinct from the other types of parapsoriasis.

Treatment. There is some evidence that injections of gold compounds are of therapeutic value.

Parakeratosis variegata. (*Parapsoriasis lichénoïde. Lichen variegatus of Crocker.*) This rare eruption is usually distributed widely over the trunk and limbs, and has a retiform arrangement, recalling that seen in livedo and erythema *ab igne*, and due, as in these, to passive dilatation of the capillaries farthest away from the arterial cones. The elementary lesions are papules, varying in colour from reddish-yellow to lilac, some of which may be flat-topped and shiny, resembling those of *Lichen planus*, whereas others are covered by scales, similar to those of *Parapsoriasis guttata*. These papules, which are closely set and tend to become confluent, are most evident on the reticulations formed by capillary stasis. The scaliness in certain areas may be diffuse. The skin of the palms may be hyperkeratotic, but the nails are not affected. Subjective symptoms are slight or absent, but some itching may be present, particularly when the patient is exposed to heat. The eruption usually develops slowly, and is essentially

chronic, but its onset is sometimes sudden and it may become widespread in the course of a few weeks.

Ætiology. Like *Parapsoriasis en plaques* this variety usually occurs in middle age, and is commoner in males. The causation is unknown.

Morbid Anatomy. There is dilatation of the capillaries, with surrounding lymphocytic infiltration, and œdema of the connective tissue. There is also some epidermal œdema without vesiculation, and the horny layer in places is parakeratotic.

Treatment. No form of treatment appears to have any curative influence on the eruption.

Parapsoriasis en plaques. (*Xanthoerythrodermia perstans* of Crocker.) Like the preceding variety this eruption is essentially chronic and unresponsive to treatment. It involves the trunk and limbs, and consists of well-defined patches which vary both in size and contour. Some are roughly circular and of the size of a sixpence to that of half a crown; others are irregular in outline, considerably larger, and may have finger-like projections or enclose islets of normal skin, thus simulating premycotic erythrodermia. Sometimes diffuse patches occur in the joint flexures. The colour ranges from pale fawn to reddish-brown, and that of a given patch may vary from time to time according to the degree of vascular congestion. The surface reveals slight exaggeration of the natural lines, thus forming a fine mosaic. It is covered by small and adherent scales, which may not be apparent unless it is gently scraped. There is hardly any infiltration, so that the patches are scarcely if at all elevated. Subjective symptoms may be absent, but some patients complain of considerable itching.

Ætiology. The condition is commoner in men than women. Although usually seen in middle age, it may begin in childhood. The cause is unknown. It is possible that it is a rare non-specific reaction of the skin to various toxins, of which, as Civatte has suggested, chiefly on histological grounds, that of tuberculosis may be one. Whitfield has described under the term "Dermatitis colonica" a similar eruption occurring in persons in whom cultures of the stools reveal an enormous preponderance of streptococci. Cure has followed the internal administration of creosote, dimol, or kerol.

Diagnosis. Confusion is most likely to arise with the circinate or flexural forms of seborrhœic dermatitis, and with the pre-mycotic stage of mycosis fungoides. In the former the lesions are more elevated, and the scales are rather larger and more easily detached; moreover they respond readily to local treatment. In the latter the patches are more infiltrated, and itching is more intense.

Treatment. Exposure to real or artificial sunlight may cause temporary disappearance of the eruption. Apart from this, it is resistant even to strong applications. Injections of a stock *B. coli* vaccine were apparently of striking benefit in one of the writer's cases.

VESICULAR ERUPTIONS

CHEIROPOMPHOLYX

(*Pompholyx*, *Dysidrosis*)

Definition. A bilaterally symmetrical vesicular or bullous affection of the hands and feet, frequently accompanied by hyperidrosis.

Symptoms. The word *cheiropompholyx* (from *χείρ*, a hand, and *πομφόλυξ*, a bubble) should be reserved for an eruption which appears spontaneously and often periodically in certain persons. A dermatitis bearing very close, if not identical, clinical appearances to those of pompholyx, may be produced by various irritant applications and by a ringworm fungus (epidermophyton), but this must be differentiated from the disease to be described.

An attack of pompholyx usually begins with a sensation of itching, burning, or tingling in the hands, and within a few hours the eruption appears as small translucent vesicles situated usually on the sides of the fingers, in the interdigital clefts, and in the palms. These vesicles are deep-seated, unaccompanied by any signs of inflammation, and have been compared to boiled sago grains. In mild cases they may remain discrete, but frequently they coalesce, forming large bullæ projecting beyond the skin. The fluid in the vesicles is clear, alkaline, and contains albumin. The lesions may dry up spontaneously, the overlying skin being shed in dry flakes; in this way the skin of the whole palm may peel off, leaving a pink new skin underneath, which gradually assumes the normal appearance. On the fingers, however, the larger vesicles and bullæ are apt to be ruptured, exposing a raw, moist, tender surface beneath. Secondary infection of the lesions is liable to occur, particularly in uncleanly persons, or in those whose resistance is low; the vesicles then become purulent, and a spreading lymphangitis of the arms with adenitis and fever may result. A peculiarly offensive odour, resembling that of atrophic rhinitis, occurs in these infected cases; this probably results from the digestion of keratin by staphylococci which, growing in the alkaline fluid of the vesicles, liberate proteolytic enzymes.

The eruption may be confined to the hands, but not uncommonly the toes and the soles of the feet are affected, and here secondary infection is the rule. In some cases the disease is accompanied by eczema of other parts of the body.

The duration of an attack varies from a few days to several weeks, but recurrences are common, particularly in spring and summer. Patients subject to the disease are usually in a poor state of health, and are frequently neurotic; the symptoms associated with chronic intestinal toxæmia of the putrefactive type are often evident, namely, pigmentation of the skin, clammy sweat, foul breath, anorexia, and headaches. There is sometimes hypochlorhydria, and the urine contains a considerable quantity of indican in the majority of cases.

Anatomy. The histology resembles that of eczema in that the vesicles are formed in the prickle-cell layer. In the corium the papillary vessels are dilated, and there is some inflammatory cell infiltration around them. According to recent researches the vesicles are formed around, and result from the bursting of the sweat-ducts in the epidermis.

Ætiology. The disease is commonest in early adult life, and is seen, perhaps, more often in women than in men. It is certainly a manifestation of toxæmia, and the frequency with which indicanuria and other symptoms of excessive intestinal putrefaction are present in patients subject to the disease suggests that the toxin may be some decomposition product of protein. Those with sedentary occupations may lose their tendency to the attacks in adopting an out-of-door life with vigorous exercise. In other cases, however, focal infection appears to be causal, since removal of infected teeth or tonsils, or thorough treatment of a chronic sinusitis, has led to cessation of the attacks. The disease occurs most frequently in hot weather, and some persons are liable to one or more attacks every summer.

Diagnosis. True pompholyx must be distinguished from eczematous dermatitis produced by external irritants, and from eczematoid ringworm of the extremities. Differentiation from these two conditions may be difficult, particularly from the latter. It is essential in doubtful cases that scales and the roofs of the vesicles should be examined microscopically, with their under-surface upward, in liquor potassæ, and interdigital epidermophytosis of the feet must be excluded.

Treatment. If, as is usually the case, there is evidence of excessive intestinal putrefaction, the diet should be revised. Patients liable to severe recurrent attacks may well become vegetarians temporarily, and in any case fruit and green vegetables should be taken rather than the heavier meats and sweets. Regular aperients are advisable for a while, such as liquid paraffin, sodium

sulphate, and occasionally calomel in small doses. If hypochlorhydria is present, dilute hydrochloric acid should be given in 30 to 40 minim doses, well diluted, after meals, as this will materially aid the digestion of protein. A thorough search for chronic foci of infection must be instituted, since their successful treatment may prove curative. Locally in the early stages sponging with a 2 per cent. solution of salicylic acid in spirit stops the irritation at once, and then either the pulv. acidi salicylici comp. B.P.C. or pasta zinci comp. B.P.C. may be applied. In cases in which the skin has become raw a lotion containing boric acid, calamine, and glycerine, should be used, and those in which secondary infection has taken place should be treated with weak antiseptic lotions locally, rest in bed, and tonics.

BULLOUS ERUPTIONS

PEMPHIGUS

The term pemphigus (πεμφιγίξ, a blister) has in the past been somewhat loosely applied to a number of bullous eruptions which ætiologically have nothing in common. Thus *P. neonatorum* and *P. contagiosus tropicus* are due to superficial pyogenic infection of the skin; *P. syphiliticus* is a bullous syphilide most commonly seen on the palms and soles of infants with congenital syphilis; and *P. leprosus* is a bullous form of leprosy.

At the present time the word pemphigus is confined to the following conditions: (1) *P. acutus malignus*. This is a rare acute infective disease, usually fatal, which occurs in those who handle dead meat, and is probably due to infection with a diplococcus. It should no longer be included in the pemphigus group. (2) *P. vulgaris*. (3) *P. vegetans*. (4) *P. foliaceus*. These are probably merely varieties of the same disease—*true pemphigus*.

Pemphigus Acutus Malignus. This disease, which is excessively rare, has been chiefly observed among butchers and farm-hands, and in most cases its onset has been preceded by local wounds on the hands or arms, through which presumably the infecting organism obtained entry. As in true pemphigus, the lesions are large bullæ, arising usually directly from the skin without any preceding erythema; they contain at first clear or slightly blood-stained serum, but later this becomes puriform from secondary infection. New bullæ arise on all parts of the body, and the mucous membranes are usually involved; the skin later becomes excoriated and covered with crusts and fœtid discharge. There is high fever, albuminuria, vomiting, and diarrhœa, and in from two to three weeks the patient usually passes into coma and dies. A few cases have, however, recovered.

The diplococcus, isolated from the bullæ by Demme, Bulloch, and others, is probably the causal organism.

Treatment. The skin should be dressed with mild antiseptic applications, and, if possible, boric acid baths should be given. Quinine is the only drug that seems to have any beneficial effect, and should be given in increasing doses.

PEMPHIGUS VULGARIS

Symptoms. The disease usually runs a somewhat chronic course. The eruption may be preceded in some people by chilliness, nausea, or pyrexia; then the bullæ appear at one or other part of the body, small at first, gradually increasing in size, tense, hemispherical, with clear yellow or slightly turbid contents. The fluid is an albuminous serum, and the turbidity is due to the presence of leucocytes. Around the bleb the skin is at first quite normal, but a narrow pink areola is acquired later, and increases in proportion to the opacity of the fluid. After a few days the fluid is absorbed, or the bleb ruptures, and shrinks down on to its base. From this it is subsequently shed; it leaves a

mark which is injected and afterwards slightly stained, but rarely or never scarred. Sometimes the bleb contains pus or blood, and after its rupture the base may be covered with yellow lymph, or may slough.

The number of bullæ in any case is very variable. There may be but few in one part, or isolated bullæ in different parts of the body; or the whole surface may be thickly covered by blebs, which come out in successive crops, lasting only a few days each, but keeping up the disease for weeks and months. Nearly every part of the body may be affected, but the hairy scalp least of all. The disease may involve the mucous membrane of the mouth, nose, pharynx, larynx, and vulva, producing raw tender areas, sometimes covered by a diphtheroid membrane; the conjunctiva, too, may be attacked, resulting in contraction ("essential shrinking"), which may lead to obliteration of the conjunctival sac and ultimate blindness.

The amount of constitutional disturbance varies according to the extent of the eruption. When this is limited the general health is usually maintained, but in generalised cases there is great pain, prostration, moderate pyrexia, and sometimes vomiting and diarrhoea. The patient presents a pitiable appearance, and, when the buccal mucous membrane is involved, even liquid food causes great pain; insomnia is a constant symptom, and the unfortunate sufferer, utterly exhausted, eventually lapses into the tremulous, maudlin state which heralds the approach of death.

Pathology. The bullæ are formed by the effusion of fluid, which collects sometimes beneath the horny layer, and sometimes beneath the whole epidermis. The fluid at first contains considerable numbers of eosinophil corpuscles, and later becomes turbid owing to the leucocytosis which results from secondary staphylococcal contamination. In the papillary layer of the skin there is inflammation with infiltration of leucocytes, many of which are eosinophil, and eosinophilia in the blood is often very pronounced. *Post-mortem* examinations have failed to reveal any constant morbid changes in the viscera.

Ætiology. Although true pemphigus may occur from childhood to old age, it is, perhaps, most frequently seen between the ages of forty and fifty. The two sexes are about equally affected. The Jewish race is particularly predisposed, whereas this is not true of dermatitis herpetiformis. It is generally believed that the disease is due to a specific infection, and various types of micro-organisms have been described and thought to be causal by different observers. Welsh has recently carried out exhaustive bacteriological investigations in seven cases, and claims to have isolated a specific strain of streptococcus, which he obtained in all cases from the nasopharynx, from the blood in five, and from blister-fluid once only. The organism is pleomorphic and Gram-positive.

Urbach and Wolfram have produced encephalomyelomeningitis in rabbits by subdural inoculation with the filtered contents of bullæ or of the blood serum in several cases of pemphigus and dermatitis herpetiformis. The animals suffered from paralysis or spastic paresis. By using a filtrate of the brain, transference from rabbit to rabbit was obtained. These experiments, which require confirmation, suggest that pemphigus and dermatitis herpetiformis are due to a specific filterable virus.

Diagnosis. The essential lesion of true pemphigus is the bulla, and the diagnosis is not usually difficult. The bullous variety of *Erythema multiforme* may lead to confusion, but the sites of predilection in this condition, the acute course, and the presence of the typical erythematous patches, should suffice to distinguish it from true pemphigus. *Dermatitis herpetiformis* in its bullous phase may be difficult to diagnose from pemphigus, but eventually the appearance of papules and small vesicles, the herpetiform grouping of the lesions, and the intense itching, will make the diagnosis clear. *Epidermolysis bullosa* may be distinguished by the localisation of the bullæ over points of pressure and friction and by the history. Confusion with bullous impetigo should not

occur. Sooner or later the phenomenon known as "Nikolsky's sign" is present. This consists of detaching the stratum corneum by the firm pressure of the finger. Moreover, at the site of pressure a bulla develops. This sign is also present in pemphigus foliaceus and in epidermolysis bullosa.

Prognosis. Probably pemphigus is invariably fatal. The patients may, however, survive for years, and may pass through periods of freedom from the eruption. In thirty cases analysed by Highman a fatal issue resulted in every one.

Treatment. The oral administration of arsenic may control the disease to some extent, but is not so effective as in dermatitis herpetiformis. A mixture containing quinine and hexamine is also of benefit in some cases. Intravenous injections of a solution of quinine (0.5 per cent.) and of salvarsan have given good results temporarily. Success has also been claimed by a method which consists of intravenous injections of iron cacodylate in the dosage of 1 grain, together with intramuscular injections of coagulen (1.5 c.c.), thrice weekly. Recently a new preparation—Germanin (Bayer)—has been extensively used, chiefly on the Continent. On the whole the reported results have been very favourable, except in patients in an advanced stage of the disease. The dosage advised is 0.5 to 1 gramme intravenously every three to five days. Toxic symptoms must be watched for, such as albuminuria and icterus. Autohæmotherapy and blood-transfusion from a suitable donor sometimes lead to striking temporary improvement, but more permanent results are likely to be obtained with Germanin than by any other known method of treatment.

The local treatment consists in keeping the skin as clean and comfortable as possible by means of boric baths, mild antiseptic creams and powders, etc. Lozenges containing cocaine and carbolic acid relieve the pain when the oral mucosa is involved. In the terminal stages morphia should be given freely.

Pemphigus foliaceus. This is a very rare and fatal form of pemphigus, in which the whole surface of the body is gradually involved. The blebs are flaccid and flat, never tense and hemispherical. Their contents are turbid, and when these escape an inflamed excoriated surface is left; to this the remains of the bullæ adhere, forming thin flakes, the under-surface of which is moist with an offensive secretion. If the flakes are removed there remains a red, raw, secreting surface, not unlike that of *Eczema rubrum*. When the whole surface is affected, it is mostly covered with the adherent epidermis, with raw patches at intervals; then also the occurrence of blebs is not easy to observe, as they form under the existing epidermis and soon rupture. The course is slow, with remissions and relapses, it may be with healing of the skin in parts; but eventually the disease is fatal by exhaustion or intercurrent disease.

Pemphigus vegetans is another rare variety, in which the mouth is first affected; then bullæ of ordinary type form on the skin, ulcerate, and remain unhealed for a long time. The characteristic feature is that in moist situations, like the axillæ, groins, and gluteal folds, fungating papillary growths form on the site of the ruptured blebs, project a quarter to half an inch above the surface, and secrete an offensive muco-purulent fluid. Severe prostration ensues, and the cases end fatally. Some relief may be obtained by local antiseptic applications. Many observers have isolated the *Bacillus pyocyaneus* from the lesions, and it is likely that the disease is true pemphigus complicated by secondary infection with this organism.

Epidermolysis bullosa. This very rare congenital and hereditary disease is one in which the skin is abnormally susceptible to trauma, so that even trivial mechanical injury results in the formation of bullæ. Two forms are recognised, the simple and the dystrophic, and the latter may be subdivided into three groups, each inherited in a different way and with differences in their clinical manifestations (54). In the simple form the bullæ heal without leaving scars, and the skin only is affected; in the dystrophic variety the mucous membranes may also be

involved, and scarring occurs. This difference depends upon the site of formation of the bullæ. In the simple form this is in the epidermis, either in the stratum corneum or rete, in the other between the epidermis and the corium.

Patients suffering from the simple form are usually otherwise normal without defects in the teeth, hair, and nails. The formation of bullæ is usually delayed until early childhood, and is rare in infancy. They occur on sites exposed to injury, *e.g.* the hands and feet, and where there is pressure from garters, suspenders or belts. The tendency often decreases or disappears at or after puberty.

In the dystrophic form, of which there is a dominant and recessive variety, the latter being the more severe, the bullæ may be present at birth or soon afterwards, and other ectodermal defects involving the teeth, hair, nails, and mucous membranes, occur, particularly in the recessive cases. The bullæ may be hæmorrhagic, scarring is severe, and a characteristic feature is the presence of milium cysts in the atrophic skin. In both the simple and dystrophic varieties hyperidrosis of the palms and soles is a common accompanying symptom.

Ætiology. The disorder is hereditary and familial, and details of many affected families have been described (54). A deficiency of the elastic tissue of the skin has been held to be the actual cause of the bullous formation, but in some cases no change in the elastic fibres has been found. Another view is that it is due to an inborn error of metabolism comparable to porphyrinuria congenita. No treatment is of any avail, except that protection from trauma should be ensured as far as possible. The bullæ, when formed, should be dressed with a mild antiseptic paste.

HYPERKERATOSES OF THE SKIN

CALLOSITIES AND CORNS

These are produced by friction and pressure.

A *callosity* consists of a hypertrophy of the horny layer of the epidermis, and is familiar on the ball of the great toe, the heel, the hands of the working man, of oarsmen and others, the tips of the fingers of those who play the violin, etc.

The *corn* (clavus) is a local thickening of the epidermis resulting in a conical downgrowth, which presses upon the subjacent papillæ, causes their atrophy, and sets up inflammation and hypertrophy in the surrounding papillæ. Corns are common, as is well known, on the toes, especially the outer side of the little toe, the dorsum and the sides of the other toes. The pain of the ordinary corn is largely due to the little plug being driven down on the cutis beneath, but spontaneous shooting pain is often present. When the corn lies between the toes and is kept constantly moist, the thickening is less marked; but the inflammation is more obvious, and the part is often extremely tender (*soft corn*). Occasionally corns will inflame and ulcerate, or a cyst or bursa forms under the corn, constituting a *bunion*.

Treatment. Corns may be cured, and almost entirely prevented, by the use of properly shaped boots. The sole should be as large as, or slightly larger than, the sole of the foot as it shapes itself in the standing position with the weight of the body upon it. If the boot sole is narrower than the sole of the foot, the upper leather will be in close contact with the edge of the foot in any movement, and constant friction will be the result. The inner edge of the sole should be straight, and pointed boots should be strictly avoided. If corns have formed, they must be treated by soaking in hot water, and shaving with a sharp knife or razor, when the dry white plug will be met with and can be removed. A corn plaster may then be worn, or the toe may be simply strapped with a good linen plaster, by which, with properly constructed boots, the friction will be reduced to a minimum. Soft corns may also be carefully shaved, and pressure removed by cotton wool between the toes, or by a turn or two of narrow strapping below

the corn. The thickened epidermis may also be removed by the application of salicylic acid, either as a 5 per cent. ointment, or as plaster, or in solution in collodion (3j to 3j). The tender part may be benefited by the use of alum or tannic acid lotions. But in all cases a sufficiently broad-toed boot, with a wide sole and a low heel, is the one requirement for permanent relief.

KERATOSIS

Keratosis, or increase of the horny layer of the epidermis, is an essential part of many of the forms of dermatitis already described, such as psoriasis, chronic eczema, and pityriasis rubra pilaris. Increase of the horny layer also results from arsenical poisoning. A rare congenital disease, in which enormous hypertrophy of the horny layer of the palms and soles occurs, is known as *keratosis* or *tylosis palmaris et plantaris*. It may occur through several generations and in members of the same family.

KERATOSIS PILARIS

This condition in its simplest form is extremely common, and may be regarded as a follicular variety of ichthyosis, in which abnormality it is, moreover, habitually present. As in ichthyosis, the parts of the skin affected are those in which the sebaceous and sweat glands are normally less developed and active, and which are consequently drier, namely, the extensor surfaces of the limbs, the calves, the flanks, and outer portions of the thighs. As a rule it is most evident on the extensor aspects of the upper arms and on the postero-external parts of the legs below the knees.

The lesions consist of follicular papules, due to the presence in the infundibular portions of the follicles of horny cones, which are very adherent. The lanugo hairs are atrophied, and traverse, coiled in spiral fashion, the cones. The colour of the affected areas may be normal, but keratosis pilaris is frequently seen in girls with acrocyanosis. In them, as a rule, there is excess of subcutaneous fat on the upper arms, thighs, and legs, and, owing to circulatory stasis, the skin of these parts, particularly on the extensor surfaces, is bluish-red, and studded with the horny plugs, around each of which is a bluish halo.

Keratosis pilaris may appear at an early age—two or three years—but is most marked in adolescence, tending to diminish or disappear in adult life. In the affected follicles the sebaceous glands and lanugo hairs ultimately atrophy completely, and the lesions are succeeded by punctiform scars.

Ætiology. Like ichthyosis, the condition is congenital and familial, and is by far the commonest variety of the inborn dyskeratoses.

Treatment. Thorough inunction with R. acidi salicylici gr. 15–25. glycerini amyli 3 2½, paraff. moll. alb. 3 2½, adip. lanæ hyd. ad 3 1 will improve the roughened appearance and texture of the skin. Thyroid gland, with or without an active ovarian extract, is indicated in some cases.

Keratosis Pilaris Atrophicans. *Kératose Pilaire Rouge Atrophiante* (Brocq), *Ulerythema Ophryogenes* (Taenzer). A more severe form of keratosis has been variously labelled by different observers. It involves the eyebrows, particularly their outer halves, the centre of the forehead, the cheeks, and the scalp. The affected parts have a reddish tint, the plugged or atrophied follicular orifices being surrounded by a halo of hyperæmia. In severe cases the scalp may become almost completely bald, and the eyebrows and eyelashes are lost.

Ætiology. Like the ordinary form of ichthyosis and simple keratosis pilaris, the condition is congenital and often familial. Cases have been recorded in which one or other parent was ichthyotic.

Keratosis Follicularis (*Darier's Disease*). This rare condition, first described by Darier in 1889, is a form of dyskeratosis, characterised by a peculiar type of degeneration of the epithelial cells, which occurs chiefly in the upper

third of the pilo-sebaceous follicles and of the sweat ducts. The same kind of cellular degeneration is also seen in Paget's disease of the nipple, and the so-called pre-cancerous dermatosis of Bowen. Briefly, the essential lesions are papules, covered by brownish crusts, situated in the dilated orifices of the pilo-sebaceous follicles and sweat ducts, and on the intervening skin. The crusts tend to become confluent, and to form verrucose patches. In the folds and joint flexures there may be vegetations, which become moist, often periodically, and emit a foul smell.

Except in the very rare instances in which the eruption is unilateral and has a segmental distribution, like a *nævus unius lateralis*, the lesions are bilaterally symmetrical, and the sites of election are the face, particularly the temples and naso-labial folds, the scalp, the aural conchæ, the pre-sternal and interscapular regions, the waist-line, and joint-flexures, but other parts may be affected. On the dorsal surfaces of the extremities there may be lesions resembling flat-warts, and there is often a punctate keratosis of the palms and soles. The *mucous membranes* of the mouth, including the tongue, pharynx, œsophagus, and rectum may be involved.

As a rule the disease appears first in early life, but the onset may be delayed until middle-age or even later. It progresses rapidly for a while, and then remains stationary.

Ætiology. It is familial and hereditary in about 50 per cent. of cases, and may appear in two or more generations. Other defects, physical and mental, may coexist with it.

Morbid Anatomy. There is hyperkeratosis, and hypertrophy of the rete Malpighii. The characteristic dyskeratotic cells—"corps ronds" and "grains,"—which Darier at first mistook for parasitic psorosperms, are seen in the rete and stratum corneum.

Treatment. Ointments or pastes containing keratolytics, such as salicylic acid and resorcin, are helpful. Striking improvement has been effected by the judicious use of the X-rays, and more recently by the Grenz-rays.

CORNU CUTANEUM

Horny growths, sometimes several inches in length, and generally twisted or bent, have in rare cases been seen. They are, as a rule, solitary. They consist of accumulated epidermic layers on a base of hypertrophied papillæ.

The **Treatment** consists of removal and cauterisation of the base.

ICHTHYOSIS

The term ichthyosis has been loosely applied to include a number of distinct conditions, all of which may be regarded as congenital dyskeratoses, but which differ as regards their distribution, severity, and mode of inheritance (54). Here only the common form (*Ichthyosis vulgaris, simplex, or nitida*) will be described. In this condition the skin is abnormally dry and covered with scales, which vary in size according to the severity of the abnormality. The parts chiefly affected are those in which the sebaceous and sweat glands are normally least active, namely, the extensor surfaces of the limbs, particularly the elbows and knees, and to a less extent the trunk, face, scalp, and extremities. The joint-flexures and natural folds, on the other hand, are hardly or not at all affected. The palms and soles have usually a characteristic appearance in that the finer lines are obliterated and the deeper ones much exaggerated. The nails are dry and brittle, the scalp is scaly, and the hair thin and lustreless. As might be expected the secretion of sebum and sweat is deficient on the affected areas, and many ichthyotics suffer considerable discomfort owing to their inability to perspire during vigorous exercise. Moreover, the lack of fat renders the ichthyotic skin extremely susceptible to the action of defatting agents, such as

alkaline soaps, soda, and hard water, so that chapping, fissuring, and eczematisation of the hands and wrists is very common in these subjects.

Although not apparent at birth, ichthyosis usually manifests itself in early infancy, and becomes more marked up to the age of about ten years. There may be some improvement at puberty, but it persists throughout life. It is frequently associated with the allergic triad of symptoms—infantile eczema, the prurigo of Besnier, and asthma. Cockayne suggests that ichthyosis and a liability to these allergic symptoms are due to independent genes lying in the same chromosome, and that there is linkage between them.

Morbid Anatomy. The horny layer is thickened and the rete Malpighii thinned. The stratum granulosum is diminished or absent. The sebaceous glands are few and small, but the arrectores pilorum are hypertrophied. Various changes in the sweat glands and ducts have been described.

Ætiology. Ichthyosis is hereditary and familial, but often skips a generation, and single cases are met with. Studies of the basal metabolic rate have not indicated hypothyroidism, but the therapeutic value of thyroid extract is incontestable.

Treatment. Alkaline soaps and other defatting agents should be avoided. Regular inunctions, at first daily and later two or three times a week, should be given with an ointment containing glycerine of starch, lanoline, and vaseline. Thyroid gland in suitable dosage should be given persistently over long periods with intervals of rest. Sunbathing has a remarkable effect on the ichthyotic skin, and may temporarily render it indistinguishable from the normal. Ichthyotics are almost invariably thin, and benefit from a dietary rich in the fat-soluble vitamins.

ATROPHIC AND DYSTROPHIC CONDITIONS OF THE SKIN

SCLERODERMIA

Scleroderma may be diffused or circumscribed. In *diffused scleroderma* there is a general hardening or induration of the skin, which begins most commonly about the face, neck, shoulders, chest, and arms, and may gradually extend to the lower part of the body. A similar condition may begin in the fingers, forming *sclerodactylia* or *acroscleroderma* (see p. 310). There is at first no change in colour, but the skin is hard, rigid, inelastic, and cannot be pinched up into folds. As it progresses the movements of the limbs are hindered, the joints are more or less fixed, the chest is limited in its respiratory movements, and if the face is affected it loses its power of expression; the mouth can be opened with difficulty, but the eyelids often retain their mobility. Subsequently the skin becomes shiny and glossy, irregular patches of pigment appear, and here and there are areas of vascular dilatation, giving a pink or violet colour. The secretions of sweat and sebum are diminished. The course of the disease is slow, and it extends over years, eventually, in many cases, subsiding entirely. During this time the patient's health is practically unaffected, but rheumatism and cardiac troubles have been noted as occasional complications. In the skin itself eczema, erythema, and ulceration may occur.

In some cases, the disease begins with more thickening or œdema of the skin, and this, according to Crocker, tends to result in an atrophied, rigid, tight condition, which is much less liable to spontaneous recovery than the simply indurated forms.

Ætiology. The diffused form is commonly associated with Raynaud's disease. Localised forms have occasionally followed injury, and more general conditions have been attributed to chills, to worry, and to the specific fevers. In recent years it has been regarded by various authors as due to disorders,

whether of excess or defect, in the internal secretions, of the thyroid gland especially, but also of the suprarenals and of the pituitary body.

The disease occurs in young adults and middle-aged persons, less frequently in children, and hitherto not under the age of thirteen months (*see Sclerema Neonatorum*). It is more frequent in women than in men, but little is known of its causes (*see Ætiology of Vitiligo*).

In *circumscribed sclerodermia*, or *morphœa*, there is an asymmetrical patch of 2, 3, or more inches in diameter, frequently corresponding to the distribution of a nerve. For instance, a patch may occur over the distribution of the supraorbital nerve on the forehead; the trunk near the breast and the limbs are also common places for the eruption. The patches are irregular in shape, or may be in the form of bands round or along a limb. They are of a dead white ivory colour, surrounded by a violet or pink zone of dilated vessels. The skin is smooth and dry, and may often be pinched up; it may be level with the healthy skin, or below or above it. The disease lasts several years, and then subsides and disappears, or it may extend into the diffused form, or persist in an atrophic condition. Circumscribed sclerodermia is also more common in women than in men, and can sometimes be referred to local irritation as a cause.

Anatomy. The epidermis is unaffected except for some pigment in the rete; there is a considerable overgrowth of connective tissue in the corium and subcutaneous tissues; the deeper vessels are surrounded by numerous leucocytes, and the superficial vessels are often contracted and empty. Leucocytes also surround and may obstruct the sweat gland ducts, and the muscular fibres of the skin are hypertrophied.

Treatment. Very little can really be done in this disease. The patient should be kept warm at all times, and tonic remedies should be given. Locally emollient applications and friction, and shampooing to restore the circulation in the skin, and galvanism may be employed. The use of thyroid extract and the application of X-rays have been followed by improvement.

Sclerema Neonatorum. This is a peculiar induration of the skin, which is either congenital or appears shortly after birth in feeble infants with deficient circulation. It may begin in the lower extremities and spread to the rest of the body, or it occurs in scattered patches on the thighs, buttocks, trunk, arms, and cheeks. The affected parts feel quite hard and firm, suggesting that the subcutaneous tissue has been frozen. The patches have a well-defined edge, are slightly raised above the surface, and sometimes have a bluish-red colour. They only pit after very prolonged pressure. The children are cold and drowsy, with small pulse and feeble respiration. They often die from collapse or diarrhœa, but occasionally recover. The cause of the change is not well understood.

It may be confounded with a true *œdema*, which occurs in similar circumstances. *œdema* affects mostly the dependent parts; the skin is blue and mottled, can be pinched up from underlying structures, and pits readily on pressure.

Treatment. The child should be kept warm and efficiently fed, by a nasal tube if necessary.

Besides senile atrophy, in which the skin becomes dry, inelastic, wrinkled and often pigmented, the following conditions may be described as atrophy of the skin.

Atrophoderma Neuritica. This, the "glossy skin" of Paget, follows upon neuritis and other lesions of the nervous system. It is especially well seen in the fingers, of which the skin becomes smooth, shining, dry, the colour pink or red, the whole finger tapering, and the nails curved longitudinally and transversely. With this is a severe and persistent burning pain.

STRIÆ ET MACULÆ ATROPHICÆ

(*Atrophoderma striata et maculata*)

Striæ atrophicæ are translucent, scar-like lines in parts of the body which have undergone considerable distension, such as the abdomen after pregnancy (*lineæ*

gravidarum, *lineæ albicantes*), the breasts after lactation, the abdomen, thighs, legs, and arms after extreme anasarca, and the shoulders, breasts, and thighs, from obesity or the presence of more localised fatty tumours. The lines are from 1 to 3 or 4 inches in length, tapering to a point at each end; they are slightly depressed below the surface of the healthy skin, but in the event of œdema or anasarca occurring in the part they project beyond it. A similar change may occur in the skin without any preceding distension, and this most commonly during some prolonged and prostrating illness, such as typhoid fever. It is then seen mostly about the buttocks, thighs, knees (*lineæ patellares*), and ankles; and the atrophic lines may be associated with circular spots, or *maculæ*, varying from $\frac{1}{8}$ inch to $\frac{1}{2}$ inch in diameter. In all these cases the skin is really atrophied, and the elastic tissue disappears; the epidermis is thinned, the papillæ are small or absent, and the subcutaneous tissue and glands are atrophied. But an early vascular, or inflammatory, or even hypertrophied, condition has been observed in the cases not related to distension; and in them the action of toxins is invoked as an explanation.

Xerodermia Pigmentosa (*Kaposi's Disease*). This is a remarkable and rare disease, which consists of combined atrophy of the skin, increased pigmentation, telangiectasis and later the growth of malignant tumours. It occurs equally in males and females, and has a tendency to affect members of the same family without being actually hereditary. Although the racial incidence is wide, it is commonest in Jews, and in a high proportion of cases there is consanguinity of the parents (54). It begins in childhood, and generally in the summer-time, with pigment spots, or with erythematous spots, which soon fade into pigment. These form over the face, neck, scalp in the temporal region, outer side of the arm and forearm, and back of the hand. The pigment spots afterwards become atrophic, and patches of white, depressed, shrunken skin form among them. These white spots are slightly contracted, and difficult to pinch up; and subsequently sufficient tightening of the skin may occur to depress the eyelids, and set up conjunctivitis. On the atrophic area there occur pink spots of dilated vessels, which gradually enlarge. The disease may remain stationary for a long time, and may never spread to other parts of the body; but eventually warty growths develop out of either the dilated vessels or the pigment spots, and these subsequently grow into tumours of an epitheliomatous nature. These fungate, discharge or bleed; and, other tumours forming in remote parts of the body, the patient is carried off by exhaustion.

Treatment can do little for this disease. As it is thought that exposure to the sun has something to do with the development of the disease, it is advisable to protect the face by thick red veils or by local applications. New growths may be excised as they arise, or be treated with radium or X-rays.

Kaposi described a *xerodermia albidum* (atrophodermia albida, Crocker) affecting the leg from the thigh downwards, and sometimes the arm down to the hand, in which the skin is atrophied and then stretched. It begins in early childhood and remains stationary.

ALTERATIONS OF PIGMENT

Increase of pigmentation is a frequent result of intense or persistent hyperæmia, through which, no doubt, there is extravasation of hæmoglobin, but the links between this and the increase of the pigment naturally in the deepest layers of the epidermis are still obscure. The most familiar instance is exposure to the sun or to the wind; but in the foregoing sections it will have been noticed how frequently pigmentation is said to follow upon the different forms of dermatitis—for instance, eczema, erythema, pemphigus, lichen, and psoriasis; to these may be added erysipelas, syphilitic eruptions and ulcerations, and especially old-standing ulcers from varicose veins in the lower extremities. The application

of blisters and mustard plasters is often also followed by staining, a fact which should make one careful how one orders these counter-irritants to the neck or arms of ladies. Another common traumatic cause of increased pigmentation is the scratching which is indulged in to relieve pruritus, especially that which results from severe prurigo, or from the presence of pediculi.

Some disorders of the skin in which hyperæmia is not a marked feature are also accompanied by pigmentation, such as scleroderma, Kaposi's xeroderma, and leucoderma, which will be described presently. As a result of internal disease, we see pigmentation of an extreme form in Addison's disease, to a less extent in some cases of lymphadenoma, in the carcinomatous cachexia, in malaria, in Graves' disease, in rheumatoid arthritis, and in some cases of tuberculosis, of diabetes, and of cirrhosis of the liver. Interference with the solar plexus has been suggested for its origin in lymphadenoma and in Addison's disease, but toxic causes are highly probable in many of the above and in some other disorders, such as chloasma uterinum; and pigmentation is well known as a result of the internal use of arsenic. It is not common to employ any special name, but the terms *melanoderma*, *melasma* (*melasma suprarenale*) and *chloasma* (from *χλοάω*, I am pale green) have been used in different instances. In all the cases which are due to a removable cause, the pigmentation will, in its absence, eventually disappear; on the other hand, it persists in incurable cases like Addison's disease, and increased pigmentation coming on in old age does not, of course, undergo any improvement. Local collections of pigment occur, as pigment moles and pigmented warts. The special forms to be here described are lentigo or *ephelis*, *chloasma uterinum*, and *ochronosis*.

Deficiencies of pigmentation are seen in albinism and leucoderma.

LENTIGO

(*Ephelis*, Freckles)

Yellow, orange, or yellowish-brown maculæ appear on the face, neck, fore-arms, and backs of the hands, from exposure to the sun under certain conditions. They are most marked during the summer-time, and fade or entirely disappear during the winter; they are first seen about the age of late childhood, and rarely in advanced life; and they affect especially people with fair hair and blue eyes (*xanthochroic* type).

Treatment. As a rule freckles are better left alone; they can, however, be removed by touching them with pure carbolic acid on a sharpened match-stick.

CHLOASMA UTERINUM

The pregnant state, as is well known, is commonly accompanied by an increased pigmentation of the nipples, axillæ, and the line between the umbilicus and the pubes. In some women, in these circumstances, a broad band of pigment forms on each side of the forehead, just below, but not touching, the margin of the scalp. It is narrower in the middle line, widens out as it reaches the temple, and may extend over the zygoma on to the cheek; it is continuous, or broken into separate small patches. The colour is yellow or brown. With it may be associated the familiar dark ring round the eyes. This frontal *chloasma* sometimes recurs with each successive pregnancy, and disappears with delivery. It may be due to other uterine disturbances—*e.g.* *dysmenorrhœa*—and sometimes no cause can be traced.

Treatment. Mercury perchloride has been most used locally, in a solution of the strength of 1 or 2 grains to an ounce of almond emulsion, applied twice daily until the skin is reddened. Zinc ointment may then be applied. Solutions of citric acid, carbolic acid, and other mild caustics, by which the epidermis is removed, and with it the pigment, have also been used. But the colour is likely

to recur. Crocker recommended salicylic acid paste, or plaster, or a saturated solution of the acid in alcohol kept on for some hours.

Ochronosis. Virchow gave this name to a rare condition, in which there is a black pigmentation of the skin, cartilages, and sclerotics; but whereas in these cases the cartilages have been constantly stained, the skin has been affected in only a few instances. The face is of coal-black or dark brown colour, darker than that of Addison's disease; the hands may present bluish-black areas, and patches have been seen on the mucous membrane of the lips. A black patch is seen in the sclerotics on each side of the cornea, midway between it and the canthus. The change in the cartilages is clinically observable in the ears, which have a bluish-grey colour, due to the blackened cartilage being seen through the thin skin; but *post mortem* the rib cartilages and the intervertebral, sternoclavicular, laryngeal, and tracheal cartilages have been found of jet-black or inky black colour.

Some tendons have been smoky brown in colour, and the cardiac valves and chordæ tendinæ discoloured in patches. The pigment is deposited in the matrix of the cartilages and in the fibrous tissue of the corium of the skin.

Some of the cases have been associated with *alkaptonuria* (see p. 510), and a few with carboloria after the constant application of carbolic acid to chronic ulcers for many years.

Albinism. This is a congenital deficiency of colour, not only in the skin, but also in the hair and in the iris and choroid. It is at once recognised by the white hair and the pink eyes; and there is commonly intolerance of light (*photophobia*), and it may be nystagmus, from the want of pigment in the fundus of the eye. It occurs in dark races as well as in the pale-faced, and in various animals—cats, mice, and others.

VITILIGO (See Plate 65, C)

(Leucodermia)

Vitiligo is an affection of the skin characterised by the depigmentation of certain areas and increased pigmentation of the zones immediately surrounding them. It is acquired, and must be distinguished from congenital leuco-melanoderma, which is nævoid in origin. The depigmented areas are milk-white in colour, oval or irregular in shape, and of varying size; their margins are sharply demarcated from the neighbouring hyperpigmented parts, the colour of which is usually of greater intensity at the edges of the white patches, fading off gradually at the periphery into the normal skin. The hairs covering the white patches may be also depigmented, or of normal colour. The pigmentary change is preceded by a transient erythema, such as is also seen in alopecia areata and circumscribed scleroderma.

The *Distribution* tends to be markedly symmetrical, and the backs of the hands, wrists, forearms, face and neck, the loins and genital organs are most frequently affected. The *evolution* appears to vary in different cases. The onset may be sudden or gradual, and the pigmentary change may slowly extend or remain stationary for years. Sunlight renders it more obvious by causing increased pigmentation of the dark areas, and thus accentuating the contrast. Partial recovery is common, but complete restoration of the skin to normal is rare. Sometimes the depigmentation becomes almost generalised.

Ætiology. Vitiligo is rare in very young children, and is seen chiefly in youth and middle age; it is commoner in the female sex. It is associated with Graves' disease, alopecia areata, scleroderma, or circumscribed prurigo in a considerable percentage of cases, and also with organic diseases of the nervous system, such as tabes, syphilitic meningo-myelitis, subacute combined degeneration of the cord, and involvement of the spinal cord or nerve-roots secondary to tuberculous caries, osteoarthritis of the vertebral joints, and spina bifida. A

familial incidence is not uncommon, as in alopecia areata. There would appear to be no doubt that both these conditions and scleroderma are dependent on involvement of the sympathetic nervous system; this view, which is supported by experimental evidence, explains the frequency of their association with Graves' disease, and the influence of shock and worry as provoking factors. The sympathetic may be involved by organic central nervous disease, or more commonly by acute or chronic infection. During the war the writer (28) observed several cases in which vitiligo was apparently provoked by pediculosis corporis; and the leucodermic patches tended to appear first on the sites of election of pediculosis, viz., the shoulders, sacral region and thighs. Whether the venom of the lice or the long-standing peripheral irritation was responsible is uncertain. Vitiligo is usually seen in persons who have several pigmented moles of varying size. The moles are often surrounded by a halo of depigmentation (leucoderma *acquisatum centrifugum* (62)).

Anatomy. Histological examination shows absence of pigment in the white patches, whereas there is excess in the epidermis and dermis of the surrounding dark areas.

Treatment. This must necessarily depend on complete investigation of each individual case. A search should be made for evidence of organic nervous disease, of syphilis, and of chronic focal infection. It has been shown that repeated exposures of the affected skin over a long period to sunlight or the carbon arc light rays will gradually restore pigment to the white areas, particularly if certain essential oils, such as oil of bergamot, which sensitise the skin to light, be previously applied.

Acanthosis Nigricans. This rare condition is of importance owing to the fact that in the majority (about two-thirds) of cases it is associated with abdominal cancer. It is characterised by: (1) diffuse papillomatosis, chiefly of the natural folds of the skin; (2) the occurrence of scattered warty lesions, which may be discrete or confluent; (3) increased pigmentation, most evident in the folds and flexures. The sites principally involved are the axillæ, the neck, the groins and internatal cleft, the umbilicus, the antecubital fossæ and popliteal spaces, the areolæ of the nipples, the submammary and hypogastric folds, the face, and the backs of the hands and feet. Diffuse warty lesions may occur on the vermilion borders of the lips, on the eyelids, in the external auditory meatuses, and on the vulva and vagina, and scattered papillomata, closely resembling ordinary warts, may be present almost anywhere on the surface of the skin. The papillæ of the palms and soles are also hypertrophied, and the tongue may have a villous appearance from a similar change. The skin as a whole may be darkened from increased pigmentation, but this is most intense in the joint-flexures and natural folds. In contrast with Addison's disease, the mucous membranes are not pigmented. Changes in the nails and alopecia may occur. The patients usually complain of itching, which may be intense.

Morbid Anatomy. Histologically there is seen papillomatosis with acanthosis, and increase of pigment, varying in degree according to the site.

Ætiology. Two types of the disorder are recognised—the adult and the juvenile. The fully developed form in adults is probably always due to malignant disease, but the writer has seen what may be called a *forme fruste* after shock or a long period of worry. In the malignant cases there is usually extensive involvement of the abdominal viscera and peritoneum. The primary growth is probably more often in the stomach than elsewhere, and the writer has seen three cases in which it was of the "leather-bottle" type. But it may be in the intestine, breast, uterus or elsewhere. In one case the condition disappeared after the removal of a deciduoma malignum. It has been suggested that it is direct involvement of the abdominal sympathetic and suprarenal glands by malignant growth that brings about the peculiar changes in the skin, but it is also possible that cancer cells produce a toxin which acts on the endocrine-sympathetic

system. In the juvenile form the symptoms are less marked and tend to remain stationary. They would appear to be due to suprarenal dysfunction, and other endocrine disorders may be present. Cases have been described in association with obesity, and this association may be familial. In other familial cases there has been a syndrome of acanthosis nigricans, severe diabetes mellitus, infantilism, imbecility, hypertrichosis lanuginosa, and cutis verticis gyrata, thus indicating multiple abnormalities of the endocrine glands.

Treatment. Nothing, as a rule, can be done for the adult cases, since the malignant disease is usually far advanced and inoperable. Improvement has been noted in some juvenile cases under thyroid medication.

AFFECTIONS OF THE SWEAT GLANDS

ANOMALIES OF SECRETION

Anidrosis, or deficiency of perspiration, is seen in fevers, in diabetes and in some diseases of the skin—*e.g.* ichthyosis and pityriasis rubra.

Hyperidrosis, or excess of perspiration, may be general or local. General sweating results from dilatation of cutaneous blood vessels, as after exercise, or from emotional causes. Sometimes, on the other hand, it occurs with contracted vessels, as in conditions of collapse or fear. General perspiration has been mentioned in connection with malaria, phthisis, pyæmia, and the crisis of acute illnesses. Local excess of sweating occurs from emotional causes and in rickets. A very troublesome form of excessive sweating is found about the hands and feet, axillæ, and genitals in some persons without any adequate cause. Some such sufferers are in deficient general health, but others are perfectly well.

The local application of belladonna liniment or the use of atropine or belladonna internally should be tried. A drop dose of liquor atropinæ will sometimes stop the sweating of phthisis for two or three successive nights. Profuse local sweating of the axillæ, and palms of the hands, has been successfully treated by the Röntgen rays. It may be also treated by the methods used for the next complaint.

Bromidrosis. This is often associated with hyperidrosis—that is, the sweat is both offensive and excessive. The experiments of Benians suggest that the odour, which resembles that of atrophic rhinitis, is due to the decomposition of keratin by staphylococci in alkaline sweat. A similar odour can be produced *in vitro* by incubating staphylococci with horn-shavings in an alkaline medium. It is not uncommon in young men or young women of the domestic class, and it may be quite independent of the general health. Thin has described a bacterium in connection with it—*Bacterium fætidum*. It is essential to wash the feet thoroughly and frequently, and use astringents and antiseptics. The socks may be dusted inside with finely powdered boric acid, and should be frequently changed, or with a mixture of salicylic acid 3 parts, starch power 10, and talc 87 parts; or the feet may be painted with a 5 per cent. solution of chromic acid, or smeared with a salicylic ointment of 2 per cent. strength, or an ichthyol ointment of 5 per cent. strength. It has been also recommended to spread glycerine or a solution of glucose over the soles of the feet, and over the toes, before the socks are put on in the morning, and to repeat this every morning as long as required. A cure may take place in three days (Benians). The rationale of this method is that the staphylococci produce acids when growing in glycerine or glucose, and the acid medium thus created prevents the decomposition of keratin.

Chromidrosis (Coloured sweating). Many of the reported cases are suspect, the discoloration being sometimes feigned and sometimes due to dye dissolved out from a garment by the sweat. Some apparently authentic cases have, however, been recorded. Blue coloration has been ascribed to pyocyanine, derived from the active growth of the *B. pyocyaneus*, and to indican. Red coloration, which is seen principally in the axillæ, is usually, at any rate, due to lepothrix (q.v.).

Hæmatidrosis, or sweating of blood, is of very doubtful occurrence.

Uridrosis is the name given to some cases in which the sweat has crystallised on the surface, and the crystals have been found to contain urea and salts.

MILIARIA

This name is given to rashes determined by profuse secretion of sweat, such that it is unable to escape by the ducts, and either raises small vesicles in the epidermis or sets up a local inflammation.

Miliaria crystallina or **Sudamina**. In this form there are small transparent vesicles, not larger than a pin's head, due to the elevation of the most superficial layer of the epidermis by accumulated sweat. They are found most abundantly on the chest and abdomen, but from their perfect transparency may be better felt than seen. The vesicles dry up, and leave a few branny scales, the remains of the detached epidermis. They are most common in phthisis and in enteric fever.

In **miliaria rubra** (q.v.), there are vesicles produced in the same way, but accompanied by inflammation. They are surrounded by a red areola, and contain a yellow, turbid alkaline fluid or actual pus.

AFFECTIONS OF THE SEBACEOUS GLANDS

Milium. This is a small bright, white, round tumour, the size of a pin's head or slightly larger, which results from dilatation either of the sweat-ducts or of the pilo-sebaceous follicles. Such little tumours are seen on the forehead, eyelids, cheeks, and genitals. Occurring in children, they were formerly called *strophulus albidus*. Sometimes they are met with in great numbers on thin cicatrices, especially those of epidermolysis bullosa. The contents are cholesterin and fatty material. When occurring in scars, they are of the nature of retention-cysts; in other cases they are cystic nævi. They can be treated by puncturing the skin and squeezing out the contents.

Adenoma Sebaceum. This is really a mixed tumour, consisting partly of an overgrowth of the sebaceous glands and partly of vascular new growth (angioma). The tumours are of small size, being seldom larger than a pea. They occur chiefly on the nose, especially the alæ, on the adjacent portions of the cheeks, on the centre of the forehead and upper lip, and more rarely as isolated lesions on the scalp and neck. As a rule their distribution is symmetrical. Their colour varies from brown to light red, according to whether the sebaceous or the vascular overgrowth predominates. Frequently sebaceous adenomas are associated with pigmented moles, telangiectases, and patches of pigment on other parts of the body, and they occur most frequently, but not always, in persons of defective mental development, epileptics, and idiots. Though of congenital origin, the tumours do not as a rule appear until some years after birth.

Treatment. The tumours can be removed by the cautery or electrolysis, and the larger ones may, if necessary, be excised or curetted out.

SEBACEOUS CYSTS

(*Wens*)

These are retention cysts arising from obstruction to the ducts of the sebaceous follicles. They are most common on the scalp, but occur on the eyebrows, face, or neck, and more rarely on the trunk or limbs. In size they vary from that of a pea to that of a nut or an orange. They are hemispherical, or more globular, uniform and smooth. The skin looks thin, and often presents well-marked vessels ramifying over it. The contents are semi-fluid or pasty, and consist of animal fats, albumin, epidermic cells, cholesterin, and earthy salts enclosed in a capsule made up of layers of epithelial cells and fibrous tissue.

The **Treatment** consists in incising the cyst, squeezing out the contents, and tearing out, or dissecting out, the cyst wall entirely; or the interior may be swabbed with pure carbolic acid.

AFFECTIONS OF THE HAIR AND HAIR FOLLICLES

Excessive development of hair—hirsuties or hypertrichosis—is common and is the cause of much distress in some women. It may be a congenital or familial characteristic, but in females may result from adenoma of the suprarenal cortex or basophil adenoma of the pituitary, or be one of the symptoms of virilism induced by a hypernephroma. In the latter case successful removal of the tumour is curative. For a full discussion of the ætiology and treatment of hirsuties reference should be made to special text-books. Deficiency or falling of the hair, known as *alopecia*, is exceedingly common. The following three conditions are quite rare: *trichorrhexis nodosa*, in which some of the hairs are found to present little nodules or thickenings due to the splitting up of the cortical fibres; it is usually caused by the defatting action of alkaline soaps and spirit shampoos; *monilethrix*, in which the hair looks beaded, and breaks readily at the internodes, so that it is only 2 or 3 inches long all over the head; and *lepothrix*, in which the hairs of the axilla, scrotum and perineum are brittle, and present irregular masses on and around them, consisting of clumps of bacteria enmeshed in a homogeneous viscid substance.

The most common *change of colour* in the hair is that known as *canities*: the hair gets successively grey and white. This is a senile change which may occur prematurely. But occasionally sudden whitening of the hair occurs after fright, intense emotion, or in consequence of neuralgia, and localised or even more or less generalised calvities may be part of vitiligo or a sequel to alopecia areata. The decoloration of the hairs has been ascribed to the presence of air-bubbles in the hair-shaft, but is probably due, as a rule, to the absence in the hair-roots of the ferment responsible for the production of pigment. The colour sometimes returns spontaneously, but nothing can be done for it.

Of the above ailments *alopecia* will be more fully described.

ALOPECIA

In dermatology the word *alopecia* is employed indiscriminately to designate fall of hair (defluvium), from whatever cause arising, the denuded areas that result from it, and even congenital absence of hair. It is derived from ἀλώπηξ, a fox, probably owing to the loss of hair in patches that occurs in this animal during the seasonal change of coat.

The following classification is arranged on an ætiological basis:—

Alopecia universalis. (a) Congenital.

(b) Acquired (generalised form of alopecia areata).

Regional and Diffuse Alopecia

I. Congenital forms.

II. Acquired forms.

(1) *Traumatic*, e.g., from friction, and from pulling of the hair (trichotillomania).

(2) *Alopecia symptomatica*.

(a) After acute infections, e.g., erysipelas, typhoid fever, pneumonia, influenza, tonsillitis, eruptive fevers, etc.; and in the secondary stage of syphilis.

(b) After surgical operations, childbirth, severe accidents, shock, and anxiety.

- (c) In association with chronic diseases, *e.g.*, anæmia, diabetes, cancer, leukæmia, mycosis fungoides, tuberculosis, and other chronic infections; endocrine disorders, *e.g.*, myxœdema, Graves' disease, ovarian diseases, the menopause, and castration in the female.
- (d) After the administration of chemical poisons, particularly thallium acetate; and metallic salts, *e.g.*, of gold, arsenic, and bismuth.
- (e) In association with certain skin diseases, *e.g.*, generalised exfoliative dermatitis, eczema, widespread ringworm.
- (f) Senile alopecia.
- (g) After the application of X-rays.
- (3) *Calvities* or *Alopecia prematura idiopathica* (male or seborrhœic form of alopecia).
- (4) *Diffuse Alopecia Areata*.

Circumscribed Alopecia.

I. *Non-cicatrical.*

- (1) *Alopecia areata*.
- (2) *Localised traumatic alopecia*.
- (3) *Alopecia following pyogenic infection*—impetigo, boils, carbuncle.
- (4) *Ringworm* (non-suppurative).

II. *Cicatrical.*

- (1) *From injuries, burns, etc.*
- (2) *Favus and suppurating ringworm* (Kerion).
- (3) *Lupus erythematosus*.
- (4) *Lupus vulgaris*.
- (5) *Tertiary syphilis*.
- (6) *Herpes zoster*.
- (7) *Scleroderma*.
- (8) *Alopecia cicatrisata* (Pseudo-pelade of Brocq).
- (9) *Folliculitis decalvans* (L'acné décalvante of Quinquaud).
- (10) *Alopecia in association with Lichen Planus and Lichen Spinulosus*.
- (11) *Keratosis pilaris atrophicans*.

Traumatic Alopecia. Alopecia areata, resulting from traumatism, will be described later.

Trichotillomania. By this is meant a morbid impulse to pull out the hair on the scalp, eyebrows, beard, or elsewhere. The hairs may be pulled out entire, leaving bald areas, or may be broken off at various distances along their shafts. It is a neurosis, and may be met with both in children and adults of both sexes. In hysterical girls it may be associated with dermatitis artefacta elsewhere. The denuded or partially denuded areas may be mistaken for alopecia areata or ringworm, but the differential diagnosis is easy. Cases are sometimes met with in which the hair is cut with scissors instead of being pulled. Psycho-analysis and psycho-therapy are, of course, necessary to achieve a cure of this neurosis.

Alopecia Symptomatica. A sudden diffuse loss of hair is most frequently caused by an acute pyrexial disease. Erysipelas in particular, with or without involvement of the scalp, is likely to be followed by a very severe fall, resulting sometimes in almost complete, though temporary, alopecia. In certain epidemics of influenza, such a loss has been a striking sequela (l'alopécie grippale), and a very large number of cases were met with and studied in those of 1918-19.

Apart from acute infections, child-birth, severe accidents, and major operations are often succeeded by a similar type of alopecia. There is an interval of about two to two and a half months (fifty-six to eighty days) between the causative event and the onset of the alopecia. Sabouraud insists that in post-infectious alopecia the temperature must have attained 103° F. or higher during several days, but he does not consider that the pyrexia itself is the direct cause of the

death of the affected hairs. It is probable that an infection of sufficient severity, like child-birth, shock, severe accidents or surgical operations, affects the sympathetic nerve-supply of the hair, and that it is upon this disturbance that the fall of hair depends.

In erysipelas, if the scalp is directly involved, the hair will fall over the affected area in about a fortnight, whereas elsewhere there will be the usual interval of about seventy days before the loss is manifest.

The prognosis in this variety of symptomatic alopecia is uniformly good, and as a rule a complete re-growth of hair occurs.

Syphilis. Syphilitic alopecia may be considered as a variety of that caused by acute infections, but it may present certain features that are pathognomonic. It occurs as a rule during the third month of the disease, corresponding in point of time to the appearance of the roscola; its onset may be delayed till the fourth and even, it is said, until the sixth month. The fall of hair is sudden and at first diffuse, but small areas almost completely denuded, quickly arise, particularly over the temples and occipital regions, which give to the scalp a "moth-eaten" appearance. This is the "*alopécie en clairières*" of the French, and is characteristic of syphilis. It is probable that these denuded areas correspond to the sites of pre-existing roseolar macules.

The severity of the alopecia varies; rarely it is so intense as to resemble at first sight a rapidly-spreading alopecia areata, but in this condition there are always present older patches of considerable size, sharply defined and completely bald, such as never occur in syphilitic alopecia.

The fall continues for three weeks, and then declines. Even if the patient remains untreated, spontaneous re-growth of the hair always takes place. Accompanying the alopecia of the scalp, a similar and characteristic fall of hair from the eyebrows is usually seen. As Sabouraud remarks, the appearances are as if the hair had been snipped irregularly with scissors. They are quite distinct from those seen in post-infectious alopecia or in alopecia areata.

Calvities (Alopecia seborrhæica vel præmatura). This form of alopecia affects the majority of males sooner or later, and occurs to a less degree and far less commonly in women. A great deal of confusion still exists as to its ætiology, which for the sake of convenience will be considered first.

Ætiology. Calvities must be considered as a secondary sex-characteristic. It may be said that the most virile type of man tends to lose his hair on the vertex of the scalp at the time of sexual maturity, while that on the face and certain parts of the body and limbs grows vigorously. In this connection it is of interest that the ancients represented the satyrs as bald on the head and very hairy on the body. On the other hand it is characteristic of the female to possess a massive growth of hair on the scalp, but (apart, of course, from lanugo hair) none on the face, nor on the body limbs except in the axillæ and pubic region. Between these two extreme types—the most virile man and the most feminine woman—there are many intermediates. It is well known that the effeminate type of man usually has luxuriant hair on the head, a relatively feeble growth on the face, and a smooth hairless skin on the body; whereas masculine woman tends to develop coarse hair on the face and body, and to have a scanty growth on the scalp. Moreover, at the menopause, when the ovarian secretion diminishes, it is the rule for the scalp to become thinned and for coarse hair to appear on the moustache and beard regions.

This influence of the sexual glands on the growth and distribution of the hair is illustrated by the fact that, as Sabouraud's enquiries revealed, *eunuchs never develop calvities*, a fact that was known to Aristotle, and by cases of virilism occurring in women with suprarenal cortical tumours. In a case of this kind observed by the writer, there occurred amenorrhœa, a rapid growth of a beard and moustache, and a loss of hair on the scalp exactly resembling the usual male type of baldness. After removal of the tumour, normal menstruation was

established, the hair on the face fell off, and a complete regrowth of that on the scalp took place. Unfortunately the growth recurred, and the signs of virilism returned before death.

Association with seborrhœa. Premature baldness in both sexes is associated with seborrhœa, although the converse is not necessarily true. It is therefore common in patients with commencing calvities to find the scalp heavily infected with pityrosporon and consequently scurfy, and the pilo-sebaceous follicles invaded by the acne bacillus. But neither of these organisms is the *cause* of the alopecia. It is true that vigorous local treatment of the scalp in these cases may diminish for a while the loss of hair, but it will never arrest it. A male, whose calvities begins at the age of seventeen, will be inevitably more or less "bald on the top" by the age of thirty, for the earlier the onset the more complete the baldness. After the age of thirty the progress of calvities is much less rapid, consequently, a man, who at thirty still has a considerable quantity of hair on the vertex, is unlikely ever to develop complete calvities.

Heredity. That there is in many cases an hereditary predisposition both to seborrhœa and to calvities is unquestionable. Conversely, certain families appear to be almost immune. Fantham has published the pedigree of a family in which all the males had calvities and transmitted it to all their sons. Cockayne suggests that in the tendency to seborrhœic manifestations the genetic factor is one that determines the development of large and active sebaceous glands, and that it is probably a simple dominant.

Symptoms and Evolution. As already pointed out, the age of onset in seborrhœic alopecia varies, and this is true of both sexes. The following description applies to a male in which it is precocious and severe. In such a case simple dry dandruff (*pityriasis simplex*) is usually present at the age of eleven; at thirteen or fourteen seborrhœa is manifest and consequently the scurf becomes greasy (*pityriasis steatoides*), and acne is likely to develop. At seventeen the hair on the scalp begins to fall, while that on the face, body, and limbs tends to grow long and coarse. There is usually sexual precocity and the boy appears older than his years. The fall of hair on the scalp is limited to the vertex, chiefly the temporo-frontal regions and the tonsure. It occurs in paroxysms, followed by periods during which it is much less, but it is always progressive. After a while it will be observed that the denuded temporo-frontal areas tend to extend backwards, separated by a central zone where the hair remains relatively long, and between them and the tonsure is another similar zone crossing the scalp transversely.

With the fall of the long hair a regrowth of new downy hairs appears, but these fall to be replaced by even more delicate and shorter ones, until eventually the affected areas become completely bald. Later, the same process involves the zones which at first were to some extent spared, so that in time the calvities is fully established, the whole of the vertex from the forehead to the occipital region becoming denuded.

During the development of seborrhœic alopecia it will be observed that the pilo-sebaceous follicles of the scalp are enlarged, so as to be visible to the naked eye, and that they are plugged with inspissated sebum, which forms the seborrhœic "cocoons," containing myriads of acne bacilli. As might be expected, comedones often develop on the bald areas.

In women with severe seborrhœa of the scalp a similar loss of hair may occur, but with certain differences of evolution. The loss is more diffuse, although, as in men, it is most evident on the vertex. The occipital region, however, is never affected. Moreover, however severe the fall may be, complete calvities never develops, and some long hair remains all over the scalp. Sabouraud has pointed out that in the later stages, more often in females than in males, a follicular sclerosis may take place, so that many follicles become obliterated.

It will be understood that the foregoing is a description of the evolution of

calvities as seen in severe cases, and that all degrees may be met with according to the individual and to the age. In many men, for example, it may not begin until late middle age, and in women until the menopause.

Treatment. This is most unsatisfactory in both sexes. It is based on an attempt to check the accompanying seborrhœa, but the results are at best only partial and never permanent. At first ointments containing sulphur, oil of cade, salicylic acid, and in dark-haired persons resorcin should be employed, *e.g.*, R. Sulphur præcip. gr. 30, Acidi Salicylici gr. 15, Vaselini Alb. ℥ 2, Ol. Coccois Nuciferae ad. ℥i, Perfume q.s. (Resorcin gr. 10 may be added), or R. Olei Cadini ℥ 2, Sulphur. præcip. gr. 30, Acidi Salicylici gr. 15, Paraffini duri q.s., Ol Coccois Nuciferae ad. ℥i, Perfume q.s. The ointment should be thoroughly rubbed into the whole scalp on three nights a week, and washed out on the following mornings. Every morning a salicylic lotion should be well brushed in:—R. Acidi Salicylici gr. 10, Ol. Lavandulae ℥ 3, Ol. Ricini q.s., Acetoni ℥ 1, Spt. Vini Meth. indust. ad. ℥i. To this Resorcin gr. 10, may be added in dark-haired persons, or euresol pro capillis in others. At the end of a month's treatment, the use of the ointment may be discontinued and a lotion containing perchloride of mercury used daily, *e.g.* R. Hydrarg. perchlor. gr. ½, Acidi Salicylici gr. 10, Resorcin (or euresol) gr. 10, Ol. Lavand., ℥ 3, Ol. Ricini q.s., Spt. Vini Meth. indust. ad. ℥i.

Local applications of ultra-violet light to the scalp also have considerable vogue, and may have a temporary effect in stimulating new hair-growth, but their value is certainly greater in alopecia areata. In the writer's opinion no treatment, however assiduously carried out, will prevent the gradual progress of calvities, particularly when it begins in early life.

Alopecia Areata. (See Plate 59, C, p. 878.) (*Area Celsi*). This form of alopecia usually begins by the sudden appearance of a bald patch on the scalp, which gradually increases in size. Frequently other patches are discovered soon afterwards either near to or at a distance from the original patch, and by coalescence large areas of baldness may result, or less commonly the hair of the whole scalp is lost. Other hairy parts may be affected, particularly the eyebrows, and the beard region in males, but the disease usually, though not always, attacks the scalp first. Recent patches of alopecia areata are pinker than the surrounding scalp, and on them the orifices of the empty follicles, often filled with sebaceous matter, are clearly visible. Older patches become pale, absolutely smooth, and depressed below the level of the unaffected parts of the scalp owing to the atrophy of the hair. At the edges of a patch, and sometimes all over it, are seen the characteristic "exclamation mark" hairs. These are from $\frac{1}{8}$ to $\frac{1}{2}$ inch in length, and their distal end is frayed out and appears thickened, while the proximal part is very thin and devoid of pigment. On extracting such a hair it will be found to come out entire and without a bulb; *i.e.* it has left its papilla and is in the process of being shed. These "exclamation mark" hairs may sometimes be seen after X-ray treatment has been given for ringworm of the scalp or after the internal administration of thallium acetate for the same purpose, but otherwise they are characteristic of alopecia areata; when, however, the fall of hair has ceased, they may, of course, be entirely absent, and their presence at the edges of the patches is evidence that the disease is still progressing. After a while new hair begins to make its appearance, as a rule in the central older parts of the patches; at first it is fair and downy, but in time it acquires the normal colouring, although in some cases it may return quite white and remain so indefinitely. As a rule, complete regrowth of hair takes place eventually, but there may be a partial return, associated with persistent baldness in certain areas, lasting for years; recurrent attacks of alopecia areata are far from uncommon, and occasionally the hair is permanently lost over part or the whole of the scalp and other hairy regions. The disease is apt to be most persistent in those cases in which a complete band of baldness is formed around the lower and posterior part of the scalp (ophiasis of Celsus).

Alopecia areata may be associated with dystrophy and atrophy of the nails, and also with leucomelanoderma (vitiligo). It also occurs in Graves' disease more frequently than can be explained by mere coincidence. Acute infections such as influenza, erysipelas, scarlet fever, and follicular tonsillitis may not only be followed by a general fall of hair, but also by typical alopecia areata.

Ætiology. At one time alopecia areata was considered to be of parasitic origin and even contagious like ringworm. Jacquet was a staunch opponent of this view, and sought to disprove it by numerous experimental inoculations on himself and others, including those already affected by the disease and therefore presumably predisposed. In not a single instance was an inoculation successful. He championed the trophoneurotic theory, and ascribed the cause in many cases to reflex irritation of the nerves supplying the affected areas by erupting or carious teeth, alveolitis, sinusitis, and chronic naso-pharyngeal infection in persons with an hereditary or constitutional predisposition to the disease. The reported epidemics in schools and institutions, which at first sight appeared to support the parasitic theory, can be explained partly, as Sabouraud pointed out, owing to an error in diagnosis between the bald patches following contagious impetigo and true alopecia areata, and partly owing to the occurrence in institutions or schools of one or a few cases of the latter, and the unconscious or deliberate production of bald patches by pulling out the hair on the part of other children, in order to excite the interest, and perhaps obtain the exemption from work accorded to the genuine cases, as in the epidemics reported by Haldin-Davis.

In discussing the ætiology of alopecia areata the relationship of the disease to vitiligo and scleroderma must be emphasised. The three conditions in fact form a closely-linked triad, since they not only occur together with some frequency, particularly alopecia areata and vitiligo, but because all three are often met with in association with disturbances of the endocrine-sympathetic system—for example, Graves' disease. The following points of similarity should also be noted: (1) All three may occur in a localised or in a generalised form. (2) They may all be seen with the so-called "band" distribution. (3) In the ætiology of all three conditions, one or more of the three factors that are known to affect the endocrine-autonomic system—namely, acute or chronic infections, reflex irritation, and psychical disturbances—appear to be of paramount importance.

The various ætiological factors that appear to be operative in the production of alopecia areata will now be considered.

Heredity. Sabouraud found that 22 per cent. of eighty-one cases stated that other members of their families were affected, and it is certainly quite common to obtain a history of an inherited or familial tendency to the disease. In a family recorded by Poynton, two brothers, a sister, and an aunt all had complete alopecia. Cockayne suggest that there are two factors—an hereditary liability and an environmental one; the former is inherited as a dominant. Dark-haired persons are affected far more frequently than fair, and, according to Cockayne, the genes for the tendency to the disease and the genes for dark pigmentation of the hair are probably carried by the same chromosome.

Age of Incidence. It is rare before the age of three years and after the age of sixty. Sabouraud states that twenty years ago its maximum incidence was between the ages of twelve and fifteen, but that now it is between twenty-two and twenty-four. In women there is a rise in incidence between forty and fifty (*pelade de la ménopause*), and several cases have been recorded after ovariectomy, and in men after castration. **Sex Incidence.** Statistics show that males are affected more often than females in the familial cases, but apart from these, the incidence is about equal in the two sexes. **Syphilis.** Sabouraud in particular has emphasised the importance of syphilis—hereditary more often than acquired—as an ætiological factor. It is in the variety already described as *ophiasis* in childhood and adult life that an inherited syphilitic taint should be suspected. Sabouraud has published many cases in which indisputable stigmata of congenital

syphilis were present, or in which the family history indicated its presence. In some of these, vigorous antisyphilitic treatment was successful in curing a long-standing alopecia. No doubt syphilis may be responsible for some instances of familial alopecia, and, in view of the profound influence that the congenital form of the disease may exert on the endocrine-autonomic system and on epithelial structures, it is to be expected that it should be a factor in some cases.

Immediate Provoking Factors. These may be tentatively classified as follows: (1) *Peripheral irritation.* In this connection the views of Jacquet have already been mentioned. Whitfield published many years ago a series of adult cases, associated with *eyestrain* and headaches, in which correction of the error of refraction led to rapid recovery. The writer believes this to be a rare but established cause. Dore has noted a group of cases in which severe and long-standing irritation from pediculosis capitis preceded the onset of alopecia areata, and these are probably comparable to cases in which *vittigo* was apparently provoked by pediculosis corporis in the war. (2) *Traumatism.* An occasional cause is an injury to the face or head, of which many cases have been recorded in France. The alopecia usually appears within a few days of the injury, but its onset may be delayed for two months, rarely longer. In one of the writer's cases, a woman who had received a severe scalp injury, the interval was eight days. Another group of post-traumatic cases is of particular interest. The alopecia is a sequel to severe and often multiple injuries to one or more limbs, with fractures and damage to the muscles and nerves, and followed by permanent changes due to involvement of the sympathetic nerve-supply—"glossy-skin," hyperidrosis, and vascular disturbances. In these cases the alopecia does not occur until several months or years after the injury, and this long interval may be explained by attributing the alopecia to an ascending nerve-degeneration, which eventually reaches the sympathetic nerve-centres concerned in the spinal-cord. (3) *Psychical disturbances.* There is no doubt that nervous shock, or a period of acute anxiety and worry are frequent predisposing causes. One of the writer's patients had three separate attacks of alopecia, the first after her mother's death, the second two years later when her father died, and the third after the death of her sister. There was a great increase in the incidence of alopecia areata during the war, both among soldiers on active service and among civilians during the air-raids ("alopecia *air-raider*," as a wag put it). In many cases following a severe shock the alopecia is of the generalised type. The latent period is very short, sometimes only a few days. Symptoms of endocrine-sympathetic disturbance indicative of hyperthyroidism ("basedowism") often accompany the alopecia in patients in which shock or long-continued worry are responsible. Lévy-Frankel and Juster recognise two kinds of alopecia areata; one, endocrine-sympathetic, with altered basal metabolism; the other, vascular-sympathetic, with normal basal metabolism. The former includes the cases in which the alopecia occurs in association with Graves' disease, latent or manifest, and those following shock or psychical disturbances; the latter the true post-traumatic cases. (4) *Acute or focal infections.* Apart from the usual diffuse post-infectional alopecia, already described, alopecia areata may be a sequel to an acute infection, such as erysipelas, influenza, pneumonia, mastoiditis, &c. Many cases have also been recorded in which a long-standing alopecia areata has yielded to the removal of chronic foci of infection in the teeth, nasopharynx or nasal-sinuses. In view of the influence of acute or chronic infections on the autonomic nervous system and endocrine glands—particularly the adrenals and thyroid—one might expect them to be a frequent factor in the ætiology of the disease.

It will be clear from what has been said that alopecia areata must be regarded as a non-specific disease in the ætiology of which various factors may be operative. The writer considers that it should be classed among the allergic group of diseases, with one or other of which it is indeed often associated. As in alopecia areata, a

local or general disturbance of the autonomic nervous system is concerned in the production of all of them, and the same hereditary or familial predisposition is apparent.

Diagnosis. The chief diagnostic features of a patch of alopecia areata are as follows: (1) Its sudden appearance; (2) The great majority of the hairs fall out completely, thus leaving the patch smooth and bald; (3) The presence of exclamation-mark hairs; (4) The absence of cicatricial atrophy.

From *ringworm* it may thus be distinguished by the fact that in the common microsporon infection of the scalp the surface of the patch is scaly, the affected hairs break off but do not fall out, so that the patch is not actually bald, and the hair-stumps are quite different in appearance from exclamation-mark hairs; microscopical examination of them will reveal the characteristic "moth-eaten" appearance, the frayed ends, and the fungus elements. Moreover, examination of the scalp under Wood's light in a dark room will demonstrate the bright green fluorescence of the infected hairs. In endothrix infection of the scalp ("black-dot" ringworm) the diagnosis is more difficult; there is no scaliness and many of the infected hairs break off at the mouth of the follicle and appear as black points, similar to those sometimes seen in alopecia areata. Microscopical examination of the extracted stumps will, however, show the large spores arranged in chains inside the shaft of the hair. From *syphilitic alopecia* the points of differential diagnosis have already been indicated. In the small patches of alopecia that temporarily surround the site of *furunculosis* of the scalp, the presence of the central scar left by the boil is sufficient. In the temporary patches following *impetigo* of the scalp the history of the infection, the presence of a few remaining crusts, and the absence of exclamation-mark hairs will aid the diagnosis. From *post-traumatic scars*, *lupus erythematosus*, *favus*, *pseudo-pelade*, and *folliculitis decalvans* the cicatricial atrophy suffices to exclude alopecia areata.

Prognosis. The majority of cases of alopecia areata recover spontaneously, but relapse is very common. Of grave prognosis are those in which rapid spread occurs until the whole or greater part of the scalp, the face, and the other hairy parts become involved. Nevertheless patients who have had complete or almost complete alopecia for many years occasionally recover.

Treatment. *General.* The treatment to be adopted in a case of alopecia areata must necessarily depend upon a complete investigation of the patient, and on a consideration of the most likely factor or factors responsible. The possibility of an inherited or even acquired syphilitic infection must always be borne in mind. Eyestrain, and the presence of a focal infection in the teeth, nasopharynx and nasal sinuses must be excluded. In many cases enquiry and an examination of the patient will reveal evidence of nervous exhaustion from shock, anxiety, a preceding acute infection, insomnia, or overwork. For these an initial complete rest followed by an outdoor holiday, a generous dietary with extra milk, sedatives, and sometimes judicious psychotherapy are indicated. Small doses of bromide with the glycerophosphates are often of value, *e.g.* R. Sodii Bromidi, gr. 5-7, Syr. Glycerophosph. Co. ℥ 1-2, Aq. Chloroformi, ad. ℥ss t.d.s., p.c. ex aqua, or luminal, gr. $\frac{1}{4}$ t.d.s., may be given instead of bromide. In some cases phosphoric acid and strychnine are more effective in overcoming the feeling of exhaustion of which these patients complain. In women who develop alopecia at the menopause active preparations of ovarian extract by mouth or by injection are worth a trial.

Local. It is very doubtful whether any local measures check the spread of a patch of alopecia, but there is some evidence that irritants which produce hyperæmia stimulate re-growth of the hair. Many such are employed, such as liq. epispasticus, carbolic acid, tincture of iodine, or tincture of cantharides and ammonia. The following is useful: R. Acidi Carbolic 1, Acidi Lactici 4. It should be painted on the patch daily until a reaction is produced, and resumed when this has subsided. Ultra-violet light, however, is admittedly more effica-

cious, and local applications, sufficient to provoke erythematous reactions on the patches, should be combined with total light-baths. For resistant patches small stimulating doses of X-rays are sometimes remarkably effective.

NEW GROWTHS IN THE SKIN

Only a small number of these will be here described. For *nævi*, *epithelioma* and *sarcoma* the reader is referred to works on surgery.

FIBROMA MOLLUSCUM

This is a soft, flaccid, wrinkled, often pendulous tumour, consisting of a covering of scarcely altered cutis and epidermis, containing a fibrous meshwork with a variable proportion of round cells and albuminous fluid. The tumours may be very few, or exceedingly numerous; they vary in size from a pin's head to the head of a man, and they occur especially on the trunk. They may apparently be congenital, but are generally first seen in early childhood. According to von Recklinghausen, they are really neuro-fibromas, starting from the fibrous sheaths of the smaller cutaneous nerves, and thence invading the fibrous structures of the vessels, the sweat glands, and the hair follicles. In an allied condition there are no separate tumours, but the skin is thickened and overgrown, or lies in large, loose, overlapping folds (*dermatolysis*). In von Recklinghausen's disease there are multiple neuro-fibromas which may be associated with diffuse pigmentation and pigmented nævoid patches varying in size from mere freckles upwards. The pigmented patches may be present alone. Very occasionally the neuro-fibromas spring from the spinal nerve roots (*see* Plate 65, A and B, p. 968).

Treatment. Removal by the knife is the only possible treatment; but if the tumours are very numerous, only such growths can be removed as are in specially inconvenient positions.

CHELOID

Cheloid is a growth of the skin and subcutaneous tissue, consisting chiefly of dense bands of fibrous tissue, containing in its earlier stages numerous spindle cells. Its more common sites are on the chest, over the sternum, on the mammæ, on the neck, back, lobules of the ears, and on the limbs. It is usually single. It begins as a flat, smooth, pink nodule, which extends laterally to a considerable size and becomes paler in the centre, while the skin around is more or less reddened. After a time bands and ridges, separated by furrows, develop, running in various directions across the tumour and into the surrounding skin. By the slow contraction of these bands much deformity may be caused, and movements of adjacent joints may be seriously restricted. The growth of the tumour is often accompanied by considerable pain and tenderness.

Similar growths not infrequently develop on former scars, such as those of cuts, burns, acne, varicella, vaccination, or small-pox. These have been called false cheloid, but it does not seem that they are essentially different. Cheloid grows slowly, and rarely disappears spontaneously. If removed by a knife or caustic, it almost inevitably returns; but it always remains a strictly local disease, invading neither lymph glands nor viscera.

Treatment. Cure has been obtained by the use of Röntgen rays, and by radium. Small cheloids may be successfully removed by repeated freezing with carbon dioxide snow.

MYOMA, NEUROMA, LYMPHANGEIOMA

These occasionally occur as cutaneous affections.

Myoma occurs in rare cases as multiple small, hard nodules, from the size of a pin's head to that of a pea or bean, on the face, trunk, or limbs. Each is a small

tumour in the corium, consisting of smooth muscular fibres (*leiomyoma*), related, apparently, in some cases to the *arrectores pilorum*.

Neuroma forms multiple, painful small growths in the course of the nerve fibres of both trunk and limbs.

Lymphangeioma is a rare growth, due to dilatation of lymphatic vessels into visible cysts and overgrowth of the intervening connective tissue. It has been seen in association with ordinary vascular *nævi*.

XANTHOMA

(*Xanthelasma, Vitiligoidea*)

First described by Rayer as "plaques jaunâtres des paupières" in 1836, this disease was called *Vitiligoidea* by Addison and Gull, *Xanthelasma* by Erasmus Wilson, and *Xanthoma* by W. F. Smith. Three varieties are now recognised, viz., *Xanthoma palpebrarum vel planum*, to which the term *Xanthelasma* is by some restricted, *Xanthoma tuberosum multiplex*, and *Xanthoma diabeticorum*.

The first is by far the commonest, and occurs, as a rule, in middle life. The lesions consist of sharply defined, yellow patches, resembling chamois-leather, and situated most frequently on the upper lids near the inner canthi. Others may appear on both lids, and by extension may rarely encircle the eyes in confluent sheets. Occasionally the nose, malar regions, the ears, and the nucha may become involved. Increased pigmentation of the eyelids and sometimes elsewhere is usually an associated symptom. Hutchinson noted the frequency of migraine in patients with *xanthelasma*, and cholelithiasis or more rarely hepatic cirrhosis may be present.

In *xanthoma multiplex* the lesions are far more widespread, and occur as papules, nodules, infiltrated plaques, *striæ*, or tumours of considerable size. They are yellow or yellowish-red in colour. Their surfaces may be smooth, furrowed or lobulated. The sites most commonly affected are the joints, particularly on the extensor surfaces of the knees and elbows and on the dorsal and lateral surfaces of the finger-joints. Symmetrical tumours may also occur in the sheaths of the Achilles tendons. On the palms and soles *striæ*, involving the natural creases and joint-folds, are often seen, and on the buttocks large tumours are not uncommon. It would appear that this distribution corresponds to parts most liable to pressure and friction, but large numbers of lesions of varying size may be widely scattered over the face, neck, trunk and limbs. Apart from the skin, *xanthomatosis* may affect the mucous membranes of the conjunctiva, mouth, pharynx, larynx, trachea, bronchi, œsophagus, and stomach. Death may result from obstruction of the trachea or main bronchi. The liver may be enlarged as a result of its involvement by *xanthomata*, and there may be a secondary cirrhosis; the lesions have also been found in the peritoneum, pericardium, and in the spleen, heart, and large vessels. Mitral and aortic incompetence may be caused by endocardial *xanthomatosis*, and familial instances of this have been described. Diabetes insipidus has been present in some cases, and attributed to *xanthomatosis* of the pituitary gland.

Xanthoma diabeticorum is a rare form which occurs usually in those who have glycosuria. It appears as yellow conical spots surrounded by a red raised area; these are seen first on the extensor surfaces of the arms, and at the lower part of the back and abdomen, and subsequently in other parts. They often subside rapidly.

Ætiology. Numerous instances of an hereditary and familial tendency to *xanthomatosis* have been described. Whereas *xanthoma palpebrarum* occurs rarely before middle-life, the other two varieties may be met with in young children. The cholesterol-content of the blood is usually raised, and the figure may be very high in *xanthoma multiplex*. It has been shown (63), however,

that the formation of xanthomatous deposits depends rather upon an abnormal ratio between free cholesterin and cholesterin-ester, or upon an alteration in the concentration of the phosphatides. These disturbances are revealed by tolerance tests, a cholesterin-fat mixture (5 grms. of cholesterin in 100 grms. of olive oil) being administered, and the quantities of free cholesterin, cholesterin-ester, phosphatides, and of total fat being afterwards estimated in the blood at intervals.

In xanthoma diabeticorum there is usually glycosuria with hyperglycæmia and hypercholesterinæmia.

Morbid Anatomy. In the flat patches the corium shows a newly formed connective tissue, with large round or fusiform cells, often multinucleated, filled with fat granules and closely aggregated fat drops (*xanthoma cells*). The nodules have a similar structure, but the fibrous tissue is more abundant.

Treatment. The smaller lesions of xanthoma palpebrarum may be successfully treated by electrolysis, but large deposits should be excised. Both in this condition and in xanthoma multiplex a low-fat dietary, with exclusion of cholesterol-containing foods, has been prescribed, but the results in the writer's experience have not been encouraging. In xanthoma diabeticorum, however, disappearance of the lesions has resulted under the influence of a suitable diet and injections of insulin.

MYCOSIS FUNGOIDES

In this rare disease, the skin is affected by a number of tumours, the appearance of which is often preceded, sometimes for years, by erythematous, eczematous, or urticarial patches. The tumours vary from the size of a bean to that of an orange, or larger. They are round, oval, or lobulated; the skin is stretched over them, tense and shining; the skin around them is often infiltrated. After a long duration some of them may shrink and disappear, others ulcerate on the surface and form fungating masses, discharging a clear watery serum. In this stage they are generally painless and free from itching or smarting. The disease lasts months or years, but ultimately the health fails, and the results have almost invariably been fatal. The view has been held that the disease is an infective granuloma rather than a sarcoma or a lympho-sarcoma; but no organisms have been found, and the tumours consist of lymphoid cells in a fine stroma of connective tissue. (*Vide also* Premycotic Erythrodermia.)

Treatment. Great improvement, though sometimes only temporary, has been recorded from the use of Röntgen rays.

DISEASES OF THE TROPICS

INTRODUCTION

MANY diseases such as trypanosomiasis, yaws, kala-azar and yellow fever are essentially tropical or sub-tropical in distribution and no one would seriously question their tropical status, but other diseases now found almost exclusively in warm climates at one time occurred extensively in temperate zones. Relapsing fever, typhus, malaria, plague, leprosy and hydrophobia were prevalent in England in the past but have now ceased to be endemic mainly as a result of applied hygiene and the improved standard of living in the community. Official figures show that from 1850-1860 the incidence of malaria at St. Thomas' Hospital, London, varied from 12 to 60 per 1,000 patients. (1) Facts such as these are not sufficiently realised and indicate that hygienic rather than climatic conditions are responsible for the high incidence of many so-called tropical diseases in tropical communities.

Another interesting aspect of this problem is the modified incidence of ordinary disease in tropical countries. Cirrhosis of the liver, for example, is ten times more frequent in the native population of the Dutch East Indies, which does not indulge in alcohol, than in Europe. Again, the type of cancer occurring in a community may be determined by local custom or disease. The habit of chewing betel-nut in Southern India has led to much buccal cancer there, while in Egypt carcinoma of the bladder and penis are frequent owing to the irritation set up by deposits of schistosome eggs in these tissues. Primary carcinoma of the liver is more prevalent in China than in other parts of the world. Again, pigment gall stones are more commonly encountered in the tropics, probably owing to hyperbilirubinæmia resulting from chronic malarial and blackwater fever, while urinary calculi are also abnormally frequent in certain parts of India. The ordinary venereal diseases—syphilis, gonorrhœa and chancroid—are common in the tropics. Two other venereal diseases, ulcerating granuloma of the pudenda and climatic bubo, also occur. Sailors visiting tropical ports may contract climatic bubo from native women, and the disease is now gradually becoming established in Europe.

Respiratory diseases, such as influenza, tuberculosis and measles, have been introduced by Europeans and have caused a high mortality amongst native races possessing little or no immunity against them. This is exemplified amongst the Polynesians where the severe ravages of these diseases have led to an appalling mortality in certain of the Pacific islands. Similarly, the stone-age aboriginals of Australia have not been able to overcome European-introduced diseases and are rapidly disappearing. Tuberculosis is also an increasing menace in India and especially in Africa (2). The primitive races of the "Dark Continent," not previously exposed to tuberculosis, tend to develop the infantile type of infection with glandular involvement and generalised dissemination which is often rapidly fatal (see p. 87). Serious responsibility lies with the white man who introduces incidentally with his culture, infections which, if uncontrolled, may lead to depopulation of vast areas of country or even to racial extermination.

The European and his Tropical Environment. Tropical countries are inhabited by oriental and native races of varying physique and character, scattered amongst whom are a limited number of Europeans and people of mixed European blood,

often possessing little immunity to the infections which are rife amongst the local inhabitants. Blood-sucking insects, arthropod vectors, flies, food and water are the usual means of transmission. The chronic carrier, especially amongst servants, proves a most potent source of danger to the European in the tropics. Where there is no densely infected native population, as in Northern Tropical Australia, the expectancy of life in European adults and children compares favourably with that encountered in temperate zones.

The difficulty of obtaining a pure water supply and a balanced dietary is another disadvantage of tropical environment. Milk is usually grossly contaminated, and if obtained from the buffalo has an unduly high fat content. Red meat may be of poor quality, and vegetables and fruit difficult to obtain. Under these circumstances vitamin reinforcement of the diet becomes essential if the effects of avitaminosis are to be avoided. The monotony of life, limitations of social intercourse and the prolonged effects of hot or moist warm climate which has little variation enervate the white man and often lead to an irritable mental state, sleeplessness and loss of concentration—a syndrome which alcohol aggravates rather than alleviates.

CLINICAL EXAMINATION OF THE TROPICAL PATIENT

A careful clinical history and physical examination of the whole patient is of primary importance in the investigation of any case from the tropics. The previous geographical habitat often affords a clue to diagnosis. Attention should be directed to the spleen, liver, colon and bases of the lungs. Amongst isolated African negroes suffering from tuberculosis, 52 per cent. showed only basal and midzonal lesions.(2) In Europeans and natives the base of the right lung must receive special attention owing to the frequency with which physical signs indicative of pulmonary congestion, collapse, consolidation or of pleural effusion occur in this situation as a complication of amœbic abscess of the liver. Similar features may accompany hydatid of the liver, but the general tendency is for the cyst to develop downwards, whereas an amœbic abscess generally progresses towards the diaphragm. Both lesions involve the right side of the liver in approximately 80 per cent. of cases.

Where any single system is implicated a particular group of diseases needs consideration in the differential diagnosis. Thus, neurological manifestations may be attributable to cerebral malaria, trypanosomiasis, cysticercosis, bilharzial granuloma of the brain or even lathyrism, while peripheral neuritis may be due to leprosy, pellagra or beri-beri. It is interesting to note that sub-acute combined degeneration of the cord, so frequently associated with pernicious anæmia, rarely, if ever, complicates tropical sprue, although megalocytic anæmia is common to both diseases. Similar examples might be cited in regard to other systems. In the endemic hæmoptysis of Japan, for example, the sputum contains not tubercle bacilli but the eggs of a pulmonary fluke, *Paragonimus westermani*. In Egypt and other parts of Africa hæmaturia is regularly caused by bilharzial disease of the bladder (*Schistosoma hæmatobium*). Enough, however, has been said to indicate the special knowledge-necessary in the clinical approach to cases from the tropics.

Laboratory Diagnosis. A wide range of infective agents produce disease in the tropics. Amongst these agents are filterable viruses, Rickettsial bodies, bacteria, fungi, spirochaetes, protozoa and helminths. The demonstration of a causal organism can be made with a frequency that is often impossible in the diseases of colder climates. Latency is a characteristic of many tropical diseases, especially those of protozoal and helminthic origin. Multiple infection is not unusual. The blood and faeces of every patient coming from the tropics should be examined for parasites as a routine procedure in addition to the usual urinary examination.

Serological methods such as the Weil-Felix reactions in typhus, the agglutina-

tion reactions for the enteric and undulant fevers and the complement fixation reactions in schistosomiasis, hydatid and *Loa loa* infestations, confirm the clinical diagnosis. Biochemical estimations are of great assistance in blackwater fever and sprue. Megalocytic anæmia occurs in tropical macrocytic anæmia, Oroya fever and sprue, and these, with other types of anæmia encountered in the tropics, call for modern hæmatological investigation.

Special Investigations. Radiological evidence is of great value in suspected liver abscess; immobility and elevation of the diaphragm, or definite upward pointing may confirm the provisional diagnosis. Similar help may be forthcoming in pulmonary amœbiasis and in hydatid disease of the liver or lungs. Calcification in the adventitia of an old hydatid cyst or in the wall of an amœbic abscess may be revealed by X-ray examination and contraindicates operative interference. Similar deposition of lime salts in other parasites may lead to typical shadows, such as calcified filarial nodules, the convoluted, moniliform outline of calcified guinea worms, the elongated, oval shadows produced by calcified cystercerci in muscle, or the multiple, oval umbilicated shadows occasioned by calcified *Porocephalus armillatus* encysted in the mesentery, liver and lungs of men. In the alimentary tract, bilharzial papillomata due to *Schistosoma mansoni* may be demonstrated in the colon by the opaque enema. In urinary schistosomiasis various complications, including papillomata, calculi, stricture of the ureter, hydronephrosis and pyonephrosis may only be evident after ascending or descending pyelography.

Sigmoidoscopy is of great importance in any tropical case with blood and mucus in the stools. It is of great value in excluding carcinoma and ulcerative colitis and in recognising the chronic types of tropical colitis due to *Balantidium coli*, amœbic ulceration or bilharzial involvement of the colon. It is, however, rarely necessary or advisable in acute bacillary dysentery. In the material obtained by gently curetting suitable lesions may be found ciliated balantidiæ, motile vegetative amœbæ containing ingested red corpuscles or lateral spined ova of *Schistosoma mansoni*.

Cystoscopy is of assistance in vesical schistosomiasis. The early lesions consist of shallow ulcers or of yellowish, round, submucous nodules or bilharzial pseudo-tubercles which become china-white when the ova are dead; later sandy patches, vesical papilloma or even carcinoma may be demonstrable. In filarial chyluria milky fluid may be seen exuding from the ruptured and dilated lymphatic varix in the base or walls of the bladder, while if of renal origin the affected kidney may be ascertained by ureteric catheterisation.

SPECIAL THERAPY IN TROPICAL DISEASE

Specific drug therapy is specially applicable to spirochætal, protozoal and helminthic diseases. Dramatic cure follows accurate diagnosis and treatment in suitable cases. The assistance that can be thus given to a patient demands and justifies the detailed clinical and laboratory investigation of any obscure disease originating in the tropics or sub-tropics. The spirochætal diseases which occur in the tropics respond to salvarsan preparations, amœbiasis to emetine, malaria to quinine, atabrin and plasmoquin, Kala-azar to the pentavalent antimony compounds and trypanosomiasis to tryparsamide and Bayer 205. Certain trivalent antimony compounds exert a specific lethal effect on schistosomes. Carbon tetrachloride and other organic preparations are very useful in eradicating certain intestinal helminthic infestations.

As in temperate climates drugs have little or no effect on the course of bacterial infections, but a valuable antidysenteric serum is available for Shiga dysentery. Potent monovalent or polyvalent antivenenes are procurable in an increasing number of countries for their indigenous venomous snakes. In Upper Egypt the mortality rate amongst children from scorpion bites has been greatly reduced by the intravenous injection of anti-scorpion serum.

HEAT-STROKE AND ALLIED MALADIES

(*Sunstroke, Heat Apoplexy, Thermic Fever, Heat Exhaustion, Sun Traumatism.*)

In the tropics, during periods of unusually hot weather in temperate climates, and under conditions such as are sometimes experienced by stokers and miners when the atmospheric temperature and humidity become unduly high, a series of maladies may arise which include heat exhaustion, heat hyperpyrexia (heat-stroke, sun-stroke) and heat cramp. The tragedy of the Black Hole of Calcutta in the hot, sultry June of 1756, where 123 out of 146 British prisoners succumbed, is a classical example of heat-stroke in Army history.

Ætiology. It has been shown (3) that, in a climate where shade temperatures approximate to those of the skin, a man performing hard manual work would need to evaporate a litre of sweat per hour from his skin to maintain his temperature balance. This is impossible unless the clothes worn are very thin and wet and a corresponding quantity of water be imbibed. Furthermore, the naked body exposed to the sun may absorb 3,420 small calories per minute, or three times its resting heat production; this is the equivalent of the extra heat that a man would produce walking at the rate of three and a half miles on the flat. Strenuous work in conventional European clothing under tropical conditions, direct exposure to the heat rays of a tropical sun, a shade temperature approximating to 110° F., a high humidity and lack of air movement are the factors leading to heat exhaustion and heat hyperpyrexia. Debilitated or alcoholic patients and those suffering from malaria, typhoid and other fevers are particularly susceptible.

Pathology. Hyperæmia and œdema of the brain and meninges, and excess of cerebrospinal fluid are found. Degeneration of nerve cells may be present. Petechiæ involving the skin and mucous membrane are common, the blood is fluid, the organs congested and the right side of the heart dilated. The myocardium, liver and kidneys show cloudy swelling. In non-sweating laboratory animals (4) hyperthermia is accompanied by a rise in the blood lactic acid and a fall in the plasma bicarbonate; in addition in sweating man there is a fall in blood chloride. It has been suggested (5) that hypochloræmia itself is responsible for the anhidrosis which can only be relieved by the administration of salt as well as water.

There are four means (6) by which a final breakdown in the thermal equilibrium between man and his environment may be brought about: (1) hyperpyrexia due to derangement of the central nervous system involving the mechanism controlling heat production and heat loss; (2) circulatory failure secondary to dilatation of peripheral vessels; (3) dehydration from fluid loss; (4) heat cramp due to chloride depletion. Unfortunately, it is impossible to forecast how any individual will react to given atmospheric conditions of heat, and the clinical picture which results may be complex and not always accurately fit into the clinical types below.

Symptoms. 1. *Heat Exhaustion.* This generally comes on suddenly with giddiness, weakness and faintness. Constipation is common. In severe cases cramps may occur. The temperature is 102° to 103° F. and lasts a few days, the pulse is rapid and weak and cardiac failure may supervene. If not appropriately treated, anhidrosis, anuria and hyperpyrexia may set in, so there is no inseparable line of demarcation between severe heat exhaustion and heat-stroke. 2. *Heat Hyperpyrexia.* The onset is often sudden, with pyrexia, convulsions and coma. In other cases the patient feels restless, giddy and dyspnoic and may suffer from nausea and vomiting. There is often frequency of micturition and sometimes urethral discomfort. Sweating diminishes or ceases altogether. Soon after these premonitory symptoms the patient became unconscious, the breathing laboured and stertorous, and the pulse rapid. Fibrillary muscular twitching and Cheyne-Stokes' breathing may develop. The skin feels hot, is

absolutely dry and may show petechial hæmorrhages. The face and conjunctivæ appear congested and cyanosis may be marked. The urine often contains albumin and indican and sometimes ketone bodies. Violent convulsions may occur frequently associated with incontinence of the urine and fæces. At this stage the rectal temperature may rise to 108° to 112° F. Knee jerks are absent. The untreated patient dies in coma with a weakening pulse and respiratory failure; if appropriately treated he may rapidly regain consciousness, though fever may persist for a few days. Convalescence is gradually established, but for some weeks great care must be taken to avoid exposure to high temperature conditions. Complications and sequelæ include persistent headache, anarthria, neuritis, chronic mental disorders and cardiac dilatation. 3. *Gastro-intestinal Type*. A gastric and also a choleraic type of heat-stroke with collapse and watery diarrhœa usually terminating fatally in three to four days have been described. 4. *Heat Cramps*. This condition, due to hypotonicity of tissue fluid secondary to loss of chloride and total base, not infrequently affects people like stokers and engineers who are doing hard muscular work in very hot atmospheres. The spasms are very painful, involve the muscles of the extremities and abdomen and may last twenty-four hours or longer.

Prognosis. The prognosis of heat-stroke depends almost entirely on the rapidity with which treatment is started. In the choleraic type and in comatose patients with temperatures over 110° F. the outlook is always grave, and even after the temperature has been reduced debilitated patients may die from collapse and heart failure.

Prevention. Protection from the heat rays of the sun by suitable topees and spinal pads, light clothing, adequate water and salt intake, the avoidance of excessive exertion at temperatures approximating to 110° F. and abstinence from alcohol before sunset are important prophylactic measures. Fever cases in the hot season should be treated in artificially cooled wards and receive several pints of citrated lemonade daily.

Treatment. The patient suffering from *heat exhaustion* is put to bed in a cooled room, purged and treated for shock when necessary. Citrates, sodium bicarbonate, sodium chloride and glucose may with benefit be added to the drinks; but, if repeated vomiting occurs, 1 to 1½ pints of normal saline (0.9 per cent.) containing 2 per cent. bicarbonate of soda should be given intravenously and repeated when thought advisable. In *heat hyperpyrexia* it is essential to reduce the temperature, and for this purpose artificially cooled heat-stroke wards have been recently constructed in the tropics. Hydrotherapy is essential. The patient is stripped naked, placed under a fan on a rush or wire mattress, and sprayed with ice-cold water. Ice is also applied to the head and nape of the neck. The rectal temperature must be taken every few minutes to control the effects of treatment, and hydrotherapy is stopped when the temperature reaches 102° F. If congestive features or convulsions are present venesection of 1 pint of blood is indicated. Iced saline enemata containing bicarbonate (2 drachms to 1 pint) should be given. Morphia or chloroform inhalations may be necessary when the fits are severe. Where circulatory failure ensues the blood volume is decreased and the blood appears viscid; intravenous injections of isotonic saline, with or without bicarbonate of soda, must be given. Collapse with low temperature should be treated by hot-water bottles and strychnine, and cardiac failure by digitalin and pituitary extract. Blood smears should invariably be made and examined for malarial parasites, and in any case where doubt exists or if the high temperature does not respond to hydrotherapy, quinine bihydrochloride (10 grains) should be injected intravenously and quinine or atebirin subsequently given *per os*. *Heat cramp* responds to intravenous injections of hypertonic saline (sodium chloride, 120 grains; potassium chloride, 6 grains; calcium chloride, 4 grains; water, 1 pint), or normal saline containing 5 per cent. glucose. It is best prevented by increasing the daily consumption of salt.

FOOD POISONING AND DIET DEFICIENCIES

Food poisoning due to infection of food with organisms of the salmonella group or *Proteus vulgaris* are more common in hot than in cold countries. Undercooked meat, fish, unboiled milk and ice-cream are the usual sources of infection. This question is dealt with on p. 367. Poisonous fungi are sometimes mistaken for edible mushrooms, and their poisonous constituents may lead to severe gastroenteritis, collapse, hepatic or even renal failure and death. *Amanita phalloides* is the only one that certainly kills. It resembles an ordinary mushroom, but is coloured olive-green on top of the cap, has white gills underneath and a cup at the base of the stem. It produces acute colicky pain, vomiting, diarrhoea and collapse followed by temporary improvement; subsequently jaundice and acute yellow atrophy of the liver may ensue. The orange or bright red coloured fungus, *Amanita muscaria*, leads to serious gastro-intestinal features, but is rarely if ever fatal. Ergotism is an example of food intoxication with a fungus which contaminates rye. Poisonous fish of the genus *Tetrodon* (Japan) contain poison in the gonads, and the roe of such fish may prove fatal in a few hours if eaten. Many other species of poisonous fish are found in tropical waters. Some, like the barracuda which are usually edible, become poisonous at certain times of the year, possibly as a result of feeding on poisonous vegetable or animal foods. Certain specific food intoxications of tropical interest will be considered in more detail.

Lathyrism. Lathyrism is a form of spastic paraplegia resulting from eating the seeds of *Vicia sativa* and possibly other closely related vetches.

Ætiology. The disease is particularly common in India, occurring mainly in the central plateau, North Behar and the United Provinces, but it occurs in France, Italy, Algeria and Persia. It occurs particularly amongst young male adults during famine periods when bread is often made from a mixture of chick pea and wheat flour. *Vicia sativa* or "akta," as it is called in India, contains a toxic glucoside base "vicine" and when fed to ducks and monkeys produces a syndrome suggestive of lathyrism (7). *Lathyrus sativus* or "khesardal" is harmless, but may be adulterated with the seeds of *Vicia sativa*. Before this was realised it was erroneously regarded as the cause of the paralysis.

Pathology. Sclerosis of the pèstero-lateral columns of the spinal cord are found, probably resulting from toxic spasm and thrombosis of arteries supplying its dorsal region.

Symptoms. The early symptoms include backache and burning pains in the lower extremities. The feet and legs become stiff, weak and tremulous, soon the thighs are involved and within ten days walking without the aid of a stick may be impossible. A peculiar spastic gait develops with adductor spasm, and in India these unfortunate people may be seen progressing laboriously along by means of a two-handed staff. When recumbent the thighs can be separated and adductor spasm ceases. Sensation is not affected, so the knee jerks are markedly increased and ankle clonus is present. Sexual impotence and incontinence of the urine and even of fæces may occur. Occasionally, in bedridden patients, cystitis develops.

Diagnosis. Milder cases at the beginning of an outbreak may not be recognised, but later the appearance of multiple cases with spinal features and a history of eating bread made from chick peas will confirm the diagnosis. Sporadic cases need to be differentiated from syphilitic and other forms of paraplegia.

Prognosis. The disease is not generally fatal, but improvement can only be expected in early stages before the cord has been permanently damaged.

Treatment. Varieties of chick pea including "khesari dal" must be excluded from the diet, which should be rich in proteins and vitamins. Damp and wet conditions must be avoided. Treatment of the paraplegia by massage, electricity and postural measures is useful, especially in early cases.

Ackee Poisoning. (*Vomiting Sickness of Jamaica.*) A disease caused by eating the arilla of unripe ackee fruit (*Blighia sapida*). (8) It frequently affects children, is often fatal and is characterised by gastro-intestinal and nervous symptoms. The ackee is found in the West Indies and the West African coast. The ripe fruit is harmless, but soup prepared from the unripe fruit is particularly poisonous.

Pathology. Visceral hæmorrhages, congestion of the meninges, and fatty degeneration in the liver are characteristic. Degenerative changes in the heart, kidneys and brain cells are also described.

Symptoms. The onset is sudden; some two hours after the child has eaten the unripe fruit, nausea, vomiting and abdominal discomfort develop. This persists for three or four hours and is often followed by a quiescent period preceding the onset of muscular twitchings, cerebral vomiting, convulsions and coma.

Prognosis. The illness is invariably fatal once nervous features have supervened, death occurring in about twelve hours.

Treatment. Scott decreased the mortality in school children from 90 to 27 per cent. by the rapid administration of rum or ether and ammonia. Alcohol precipitates the poison both *in vitro* and in the stomach.

Atriplicism. This disease occurs in North China amongst the poor who eat the shoots of the weed *Atriplex littoralis*, in times of famine. Some say the disease is caused by small insects on the plants. After twelve to eighteen hours from eating the shoots there is tingling of the fingers followed by local œdema and itching of the hands, forearms and face, which may last a week or more. Anæsthesia of the digits may develop and heat sensation is increased. Vesicles and skin ulceration may follow. The disease may be confused with Raynaud's disease or erythromelalgia. Medication consists of saline purgatives.

Favism. This disease, which is not completely understood, is said to follow the ingestion of fresh beans of *Vicia fava* or even exposure to the flowering plant. The illness develops only when the beans are ripening. Personal idiosyncrasy is marked as everyone exposed is not affected. Cases have been reported from Italy, Greece, Mesopotamia and elsewhere.

Symptoms. Shortly after ingesting the beans, fever develops with hæmolytic anæmia, jaundice, hæmoglobinæmia and hæmoglobinuria. The red blood corpuscles may decrease rapidly to 2,000,000 per c.mm. with an even greater fall in hæmoglobin. Renal involvement may follow. Recovery is the rule with adults, but the disease may be rapidly fatal in children.

Treatment. Purgation when the beans have been recently ingested, abundant fluids by mouth and rectum, the administration of citrates and sodium bicarbonate per os and blood transfusion when signs of anoxæmia develop, appear rational procedures.

The various vitamin deficiency diseases such as pellagra, beri-beri and epidemic dropsy encountered in the tropics and sub-tropics are considered, pp. 569 *et seq.*

TROPICAL MACROCYTIC ANÆMIA

(*Tropical Megalocytic Anæmia, Tropical Anæmia of Pregnancy.*)

A severe megalocytic, hyperchromic anæmia of nutritional origin especially affecting pregnant native women in the tropics; it responds specifically to the administration of marmite and liver extract with a reticulocyte response and rapid blood regeneration.

Ætiology. Though not unknown amongst males the disease mainly occurs in pregnant women and has been reported in native populations resident in India, the Malay States, China and the West Coast of Africa, where the diets are known to be unsatisfactory. The age incidence is generally between fifteen and thirty years, and whites are rarely affected. Marmite, which is an autolysed

extract of brewers' yeast, cures the condition, and it (9) has recently been shown that vitamin B₁, B₂ and B₄ are not responsible for the therapeutic response and that the curative factor probably arises from protein breakdown during autolysis. The morbid anatomy has not been satisfactorily investigated.

Symptoms. Signs and symptoms, mainly due to the anæmia, consist of weakness, palpitation, shortness of breath, pallor, low blood pressure and cardiac murmurs. Fever, œdema of the feet and puffiness of the face are frequent. Sore tongue, vomiting, diarrhœa and enlargement of the liver and spleen may also occur, but intercurrent infection with malaria, amoebiasis and ankylostomiasis may be responsible for certain of these features.

The red cell picture and Price-Jones curves resemble pernicious anæmia. Often the erythrocytes are reduced below 1,000,000 per c.mm., but the hæmoglobin is not correspondingly reduced, so the colour index generally exceeds unity. Anisocytosis and megalocytosis are marked and both normoblasts and megaloblasts may be present. The serum bilirubin, however, is not increased in uncomplicated cases. Free hydrochloric acid is usually present in the gastric juice.

Diagnosis. The presence of megalocytic anæmia in pregnant white women will generally suggest sprue or pernicious anæmia, but these diseases rarely occur in the native populations under consideration.

Prognosis. Liver treatment has lowered the mortality from 40 per cent. to 33 per cent. and the recent introduction of marmite has caused a further reduction.

Treatment. Prevention depends on the institution of a balanced diet adequate in vitamins. Once the disease has developed, rest in bed, and the administration of marmite in a dosage of 1 teaspoonful four times daily, is indicated. In a favourable case a rapid reticulocyte response occurs about the fifth to seventh day and rapid blood regeneration follows. Intercurrent infections require appropriate treatment.

TROPICAL DYSFUNCTION OF THE GASTRO-INTESTINAL TRACT

TROPICAL SPRUE

(*Psilosis* ; *Cochin-China Diarrhœa* ; *Diarrhœa alba*.)

Tropical sprue generally affects adult Europeans or those of mixed European stock after some years of residence in endemic areas. Hot, damp, coastal climates favour its development and it is especially common in India, Ceylon, the Federated Malay States, Java, Cochin-China and Porto Rica. It may directly follow on hill diarrhœa and is not infrequently preceded by a history of dysentery or of chronic malaria necessitating prolonged quinine administration. Children in the first decade are not affected and, Porto Rica excepted, native populations rarely develop the disease. Peculiar features are its patchy geographical distribution, its absence from Africa and its occasional onset in tropical patients after many years of residence in Europe. Ashford (1915) regarded it as a moniliasis of the digestive tract engrafted on an unbalanced dietary. Scott (1923) postulated parathyroid deficiency, while Elders (1919) regarded it as a primary deficiency disease due to lack of vitamin A and B and amino acid. Castle and Strauss (1932) recently suggested its classification along with pernicious anæmia as a conditional deficiency; they regarded vitamin B₂ as the source of intrinsic factor.

Sprue arises as a metabolic breakdown of the gastro-intestine in which there is generally defective secretion of Castle's intrinsic factor, and malabsorption of fat, calcium and glucose in the small intestine. The possible factors under-

lying this breakdown are (1) unbalanced dietary; (2) preceding tropical infections, some of which have been already proved to depress gastric secretion; (3) prolonged residence in a humid climate which involves an increased distribution of blood to the skin at the expense of the alimentary tract. A diet rich in fat and carbohydrate and poor in first-class protein, which is the main source of extrinsic factor, is known to precipitate relapses in sprue and may possibly prove the most potent single factor in the initiation of the disease.

Pathology. No primary pathological lesions are found in the stomach and small intestine. The characteristic findings are disappearance of subcutaneous fat and wasting of muscles, a smooth atrophic tongue, thinning of the intestine, a small heart showing brown atrophy, decrease in the size of the spleen, liver and other viscera and megaloblastic hypertrophy of the red marrow similar to but generally less extensive than that seen in pernicious anæmia. Intestinal ulceration and occasional perforation with peritonitis may be encountered as complications.

Symptoms. Early features of onset may include (1) sore tongue and buccal aphthæ; (2) dyspepsia, abdominal distension and intestinal flatulence; (3) morning diarrhœa: typically, several pale, bulky, fatty, gaseous stools are passed before noon, after which the patient often enjoys relative comfort. The lingual features may precede or follow the bowel condition but in some cases of recurrent sprue they may not appear for many years. As the disease progresses marked loss of weight, asthenia and anæmia of megalocytic type develop. Apyrexia is the rule, the temperature generally being subnormal. Fever, however, may be present for the first day or two in the initial attack, but its recurrence at a later date or during relapses should arouse suspicion of intercurrent infection or some complication such as intestinal ulceration.

The well-established case of sprue presents a definite clinical picture. Emaciation is marked. The skin is dry, wrinkled and often of a parchment-like consistency and patchy pigmentation may appear over the forehead, malar eminences, buttocks and elsewhere. The mucous membranes are pale and the nails are rigid and brittle. The appearance of the tongue varies from time to time: it is invariably clean and in the early stages may show prominent papillæ, painful, red, inflamed patches, fissures and apthous ulcers; later the papillæ disappear and the tongue becomes smooth, pale and atrophic. Distension of the abdomen is an outstanding feature, and its walls are often so thinned that peristaltic movements in the distended coils of intestine are obvious on inspection. Unlike pernicious anæmia the spleen is not palpable in uncomplicated sprue, while the liver usually appears decreased in size on percussion. The systolic blood pressure is low, not infrequently being less than 100 mm. Hg.; hæmic murmurs sometimes develop. The knee jerks and other tendon reflexes may be decreased or absent. Paræsthesia and blunted sensation may result from peripheral nerve changes, while in cases complicated by tetany, excessive muscular irritability is readily disclosed by Trousseau's and Chvostek's signs.

The total fæcal fat is increased from 25 to 70 per cent., but the fat itself is split normally, while the glucose tolerance test often shows a flat or low curve, or a delayed rise indicative of defective absorption. The excessive bulk of the stool in sprue is due to its large fat residue, while its acid and gaseous characters are attributable to fermentation of glucose which has been inadequately absorbed; the pale colour is dependent on the high fat content as well as on the transformation of the normal fæcal pigment—stercobilin—into a colourless derivative—leucobilin. Hypochlorhydria and achlorhydria are common, but acid secretion follows the injection of histamine in at least 70 per cent. of cases, a test which may prove of value in differentiating sprue from pernicious anæmia; hyperbilirubinæmia is also less marked in sprue. Hypocalcæmia is often observed, and where the blood calcium falls below 7 mg. per 100 c.c., tetany supervenes.

Sprue anæmia is megalocytic in type, and though it is not as severe as in

pernicious anæmia in the primary attack, it may become so later in relapses. The Price-Jones curve is asymmetrical, shows displacement to the right, with broadening of the base; there is an increase in the average diameter of the corpuscle.

Course. Though sprue may occasionally prove fatal within six months of onset, it generally runs a very chronic course with spontaneous remission and relapses, which may be brought on by indiscretions of diet containing an excess of fat, carbohydrate or condiments, or by chill, respiratory infection and other intercurrent disease. There is a tendency to natural cure provided the patient leaves the tropics, and it is well to remember that many cases of sprue recovered with alimentary rest in a cool climate prior to the introduction of liver extract therapy; in this respect sprue again differs fundamentally from pernicious anæmia.

Complications include anal fissure, hæmorrhoids, femoral and other thromboses, neuritis, eczema, intestinal ulceration and rarely perforation of the small or large intestine.

Diagnosis. Other megalocytic anæmias, especially those associated with tropical macrocytic anæmia, pernicious anæmia, gastro-jejuno-colic fistula, intestinal ulceration with stricture and tuberculous ulceration with fistulæ may lead to confusion. Diseases giving rise to fatty diarrhœa such as idiopathic steatorrhœa, abdominal lymph-adenoma and tuberculous adenitis involving the mesenteric glands and causing lymphatic obstruction, and interstitial pancreatitis may occasionally need differentiation. In the diagnosis of atypical sprue clinical experience combined with a careful case history, physical examination and detailed laboratory and X-ray investigation may prove essential.

Prognosis. With modern treatment the patient is generally convalescent and the blood restored to normal within two months. Return to the tropics can be permitted with reasonable safety after six months' freedom from symptoms in those under fifty-five years of age; relapses, however, may occur even after many years of good health.

Treatment. The patient with sprue must be put to bed on an appropriate diet for a period of five to eight weeks and receive liver extract in full dosage if anæmic. On admission oleum ricini (2 drachms) is given, and where the diarrhœa is severe, pulv. bataviæ co. ($\frac{1}{2}$ to 1 drachms t.d.s.) may be prescribed. Bed rest is essential as it halves the calorie requirements of the patient and permits alimentary rest which is of fundamental importance in recovery. Several different diets have been advocated empirically, including the fruit diet of van der Burg, the milk diet of Manson and the red meat diet of Cantlie. On the basis of the biochemical findings a graded series of high protein diets low in fat and carbohydrate have been introduced successfully, the ratio of these different constituents being 1.0 of protein : 0.3 of fat : 1.3 of carbohydrate instead of the usual 1.0 : 1.0 : 4.0 (10). The energy value of the first diet = 600 calories, that of the last = 3,000 calories, and the dietary is gradually increased as the diarrhœa and other alimentary features improve. Lean red meat is the main source of protein, but a defatted high protein milk powder (sprulac) (11) is also available. A convalescent high protein diet and vegetables can generally be allowed about the fifth week, and thereafter the quantity of fat and carbohydrate is gradually increased.

The anæmia is almost invariably of megalocytic type and generally it is hyperchromic. Provided the diarrhœa be controlled by suitable dietary, as indicated above, liver extract by mouth is adequately absorbed and reticulocytosis and rapid blood regeneration follow as in pernicious anæmia. Liver extract should be given in a dosage equivalent to $1\frac{1}{2}$ lb. of whole liver daily for the first month, in a dosage equalling 1 lb. for the second month, and in a dosage of $\frac{1}{2}$ lb. for the third month or until such time as the blood picture has attained complete normality. In severe chronic cases a maintenance dose for

several months or even one year is occasionally advisable. Occasionally retractory cases are encountered where reticulocytosis is submaximal and improvement inadequate; here oral treatment should be reinforced or replaced by large doses of liver preparations given parenterally, such as Campolon 6 c.c. daily for fourteen days. In those rarer cases where hypochromia is present and the colour index is low, or where there is an undue lag in the production of hæmoglobin following liver extract therapy, complications or intercurrent disease should be suspected. Iron in the form of freshly made Blaud's pills (5 grains) should be prescribed, commencing with two and working up to four pills thrice daily after food, or, alternatively, ferri et ammon. cit. (30 grains) may be given thrice daily after meals. When the secretion of HCl is found defective acid hydrochlor. dil. (B.P.) in doses of 1 drachm should be administered in orange juice thrice daily after food.

Tetany with hypocalcæmia calls for calcium salts such as calcium lactate, 40 grains, thrice daily, and in addition a diet low in fat is essential since calcium cannot be satisfactorily absorbed while there is an excess of fat in the stools.

Once well, the sprue patient must continue with a well-balanced diet adequate in vitamins and first-class protein, and avoid rich, spiced and sugary food and condiments. Aperients should be taken with caution and chill and respiratory infections guarded against as far as possible.

Hill Diarrhæa. A disease of high altitudes affecting Europeans who have gone to hill stations during the hot weather.

Ætiology. It occurs during the rainy season at heights over 6,000 feet in hill stations, in India, Ceylon and South America; it probably results from a physiological breakdown of the gastro-intestinal tract under conditions of low barometric pressure and high humidity. Europeans of all ages and both sexes are susceptible, and during particularly wet seasons epidemics have occurred in which a large proportion of the hill population have been affected. Nothing authoritative is known of the pathology, or of its clinical biochemistry.

Symptoms. Diarrhœa commences about 4 to 6 a.m. and is followed by three to six urgent actions of the bowels before mid-day, after which the patient is generally comfortable. The stools are copious, pale, like pipe-clay and of a frothy, fluid consistence. Some state there is an excess of fatty acid, soaps, undigested food and yeasts. Flatulence, borborygmi and abdominal distension are troublesome and if the condition persists, anorexia, dyspepsia and considerable loss of weight ensue. Lingual features are absent.

Prognosis. The condition is never fatal, but it may be very distressing and necessitates a return to lower altitudes. A certain number of cases develop into typical sprue after returning to the Plains.

Treatment. Rest in bed, warm clothing, the avoidance of chill and a milk diet are advised. Oleum ricini ($\frac{1}{2}$ ounce) should be given at onset and acid hydrochlor. dil. B.P. (1 drachm) after food. From its resemblance to sprue a high protein, low fat, low carbohydrate diet, such as sprulac, would appear preferable to a milk diet liable to contain an excess of fat.

INFECTIOUS DISEASES OF THE TROPICS

Diseases due to Filterable Viruses

There are a number of predominantly tropical diseases such as hydrophobia, yellow fever, dengue, sand-fly fever, Rift Valley fever and climatic bubo which fall into this category. The outstanding characteristics of the viruses are firstly, that they are ultramicroscopic, measuring less than 250 $\mu\mu$ in size and so fail to be resolved by the ordinary microscope, and secondly, that they pass through filters which are usually impervious to bacteria. Some of these diseases like yellow fever, dengue and sand-fly fever are insect borne, others are transmitted

directly ; climatic bubo for instance is acquired during coitus, and hydrophobia by the bite of an infected canine. Complement fixing and protective antibodies may be found in the serum. In distemper and yellow fever, immunisation by means of virus and antiserum has been introduced. With the exception of rabies, however, killed virus produces little or no immunity. For small-pox, see p. 28.

HYDROPHOBIA

(*Rabies, Lyssa*)

An infective disease occurring as an epizootic amongst canines due to a filterable virus which is present in the salivary glands and central nervous system. It is generally transmitted to man and other warm-blooded animals by the bite of an infected dog or by its licking a freshly abraded skin surface ; jackals and wolves also transmit the disease in the East. In Central and South America, the transmission to man and stock by infected blood-lapping bats has been recently demonstrated. The disease itself has been known from ancient times, reference being made to it in the writings of both Aristotle and Celsus.

In dogs there are two forms—"furious" and "dumb" rabies—but neither is ever accompanied by the hydrophobic syndrome observed in man. The first indication of disease generally appears some three to six weeks after the bite and consists of a decisive change in temperament, while later signs of irritation or vicious fury develop with staring coat and a tendency to bite wildly at living or even inanimate objects. Ordinary food may be refused, while earth, straw, clothes, etc., are eaten with avidity. This stage lasts from a few hours to two or three days. Later, difficulty in swallowing develops, leading to dribbling of saliva and a peculiar bark, change in the note of which is often erroneously attributed to a "bone in the throat" ; futile and dangerous attempts may be made to remove it. As the disease progresses the lower jaw drops, the hind limbs and tail become paralysed, the gait unsteady, and finally, the animal collapses and dies with asphyxia two to five days after the onset of symptoms. In "dumb" rabies there is no stage of fury or excitation, paralysis setting in early.

Ætiology. Pasteur in 1881 discovered that the virus of rabies could be transferred from one animal to another in series by direct brain inoculation. During this process in rabbits it was noted that after some twenty passages the incubation period of street virus which varies from eight to sixty days was reduced to seven days. This is known as virus fixé or fixed virus, and, despite its enhanced virulence for rabbits when inoculated directly *viâ* the brain, it fails to produce the disease in either experimental animals or man on subcutaneous injection. Street virus is transmitted *viâ* the peripheral nerves to the central nervous system and is present in emulsions of the parotid and submaxillary glands as well as in the milk of lactating women. Brain emulsions are not filterable, but salivary virus passes readily through Chamberland F. filters. The infectivity of saliva is much greater than that of the brain or spinal cord.

Morbid Anatomy. Post-mortem examination reveals injection of the pia arachnoid, a few petechial hæmorrhages and an excess of cerebro-spinal fluid, while microscopic examination shows leucocytic infiltration of the perivascular lymph spaces and Negri bodies within the cytoplasm of the nerve cells. These important structures, described by Negri in 1903, are globular or oval in shape, of very variable diameter (0.5 to 25 μ) and commonly located in the hippocampus and the Purkinje cells of the cerebellum. Though demonstrable in 97 per cent. of dogs with street rabies they are never found in the salivary glands. By some they are regarded as of protozoal nature, but more probably they originate as pathological degenerations or cell inclusions.

Symptoms. The incubation period generally varies from four to eight weeks, the limits being eleven days to a year or longer. As the virus travels

viâ the nerves, face, head and neck, bites have a shorter incubation period than those involving the arm, and arm bites a shorter incubation than those implicating the leg.

The onset is generally sudden, but prodromal features may be noted for a day or two and include local pain in the scar, fever, anxiety, restlessness, insomnia, irregular and sighing respiration and phases of rushed speaking. ✓

The hydrophobic syndrome itself consists of sudden spasmodic attacks involving the muscles of the pharynx, larynx and, indeed, the whole respiratory tract. In the early stages such an attack may be induced by offering the patient a drink. As the glass is lifted to the mouth the head is retracted in a series of spasmodic jerks accompanied by gasping respirations, and any water reaching the mouth is expelled. During the attack the shoulders are raised, the chest expanded and the sternomastoid and platysma muscles contracted. Later, even the suggestion or thought of drinking suffices to bring on a paroxysm, while external stimuli such as sudden sounds, a draught of cool air, flashes of light and strange smells have the same action. The voice becomes altered and raucous, and, owing to the dysphagia, tenacious mucus and frothy saliva collect in the throat and on the lips, and during paroxysms are flung about the room. Feelings of terror or accesses of fury may accompany the attacks, but in the intervals the patient generally lies quietly at rest and the mentality is clear. Extension to the general musculature leads to rigidity and arching of the body, and respiratory spasm may result in sudden death from over-distension of the right heart. During this stage of excitation the temperature is raised, the face flushed, vomiting is common and exhaustion and emaciation marked. The reflexes are increased and glycosuria not uncommon. Near the end, the spasms may ameliorate or cease entirely.

Should the patient survive this excitation, depression very occasionally ensues with various paralyses, including paraplegia, hemiplegia and Landry's ascending paralysis, followed by fatal coma.

Diagnosis. This generally presents little difficulty, especially if the disease in the dog has been confirmed. Typhus fever may be accompanied by hiccup, pharyngeal spasm, dysphagia, neuro-muscular excitability, lymphocytosis and increase of globulin in the cerebro-spinal fluid; here the clinical history, the absence of rash and negative Weil-Felix reaction will assist. Lyssaphobia, which is an hysterical manifestation unaccompanied by fever, generally develops well within ten days of the dog bite, while the absence of trismus and the presence of dysphagia should distinguish rabies from tetanus. Bulbar paralysis from any cause and cases of datura and other forms of poisoning in India have occasionally caused difficulty. The disease in the vector can be confirmed by demonstrating Negri bodies or by subdural inoculation of rabbits with brain emulsion.

Prognosis. The death rate in untreated cases is variously estimated as from 5 to 33 per cent., while in those having early anti-rabic inoculation it is considerably lower—about 1 per cent. The mortality varies with the location of the bite—it is highest in face bites—the number of tooth marks, the depth and degree of tissue laceration, the interposition of clothing and the rapidity and type of local treatment adopted (12). The earlier anti-rabic vaccine is inoculated, the better the prognosis.

Prevention. The prevention of rabies in England has been carried out by (1) the muzzling order; (2) restricting the movement of dogs; (3) strict quarantine of all imported dogs. In endemic areas all bites from canines should receive prompt local treatment. A suspected dog should never be destroyed; it should be muzzled and kept under observation for ten days. If alive and well at the end of this period the bitten person cannot have been infected and does not require treatment. This rule, adopted at all Pasteur Institutes, is based on the observations that the saliva of a rabid dog is never infective more than four days before the onset and that an infected animal never survives longer than six days after

symptoms appear. In definitely bitten cases it is safer to commence treatment at once, especially in face and neck bites, and to discontinue if the dog survives. The virus of rabies does not pass through the intact skin, so the question of inoculating a person licked by a suspected dog only arises if recent abrasions be present. Should the person be seen at this time the abrasion should be washed with permanganate solution and cauterised; in these circumstances anti-rabic inoculation need be given only when there are face or neck abrasions or the animal develops symptoms, dies or has escaped.

Treatment. (1) *Local.* If seen within half-an-hour of the bite, a ligature to facilitate bleeding by stopping venous return, should be applied and the parts washed with permanganate solution. Each tooth-mark should be probed and cauterised. Wounds, especially those of the face, must not be sutured for at least three days. (2) *Anti-Rabic Vaccine.* The principle is to immunise the patient against the disease before the virus implanted in the wound reaches the central nervous system; the longer incubation period of the street virus makes this possible. Five vaccines are in use. During the period of inoculation the patient is instructed to rest and to avoid alcohol. The Pasteur vaccine is the attenuated virus prepared by drying, for varying periods at 22° C. under potash, the cords of rabbits sub-durally inoculated with infected brain emulsions. Eighteen injections are given of emulsions of cords dried from fourteen to three days. With Högye's method the virus is attenuated by dilution; saline suspension of fresh medulla, 1/10,000, is first used and gradually increased to 1/100. Semple's carbolised vaccine consists of a 1/200 brain suspension in 0.25 per cent. phenol and 0.85 per cent. saline; a full course of treatment is fourteen daily subcutaneous injections of 5 c.c. Etherised vaccines may cause more severe local reactions, though paralytic sequelæ are less frequent than after carbolised ones. The most potent vaccine, now used in India, consists of a 5 per cent. carbolised emulsion of sheep brain infected with Paris virus. In mild cases 2 c.c. of this vaccine is given daily for seven days, in the average case 5 c.c. for fourteen days, while in severe cases such as children bitten on the bare skin, in face and neck bites and in jackal and wolf bites, an intensive course of fourteen daily injections of 10 c.c. each is advised. Cutaneous reactions take the form of itching, tender swellings surrounding the inoculation site and appearing about the eleventh day. Paralytic accidents are, fortunately, infrequent though their incidence is the same after either living or dead vaccines. Facial neuritis, dorso-lumbar myelitis and an ascending paralysis of Landry's type which has a mortality of 30 per cent. may be encountered (13).

Treatment of Paroxysms. Neither chemotherapy nor specific anti-rabic serum is of value and all that can be done is to alleviate the suffering of the patient by good nursing and sedative treatment. Morphia, hyoscine, chloral, chloroform inhalations, atropine and even curare have been employed. Intravenous barbiturates may find a sphere of utility here. Tetrado-toxin, $\frac{1}{2}$ to 1 c.c. every four hours, has been used extensively in India for the relief of spasms.

YELLOW FEVER

(*Yellow Jack, Black Vomit, Typhus Icteroides, etc.*)

An acute infectious disease occurring mainly in West Africa and parts of tropical America, caused by a filterable virus which is transmitted by the bite of the tiger-banded mosquito, *Aedes ægypti* (*Stegomyia fasciata*).

Ætiology. The disease is widely endemic in West Africa and like intestinal schistosomiasis (*S. mansoni*) was probably transmitted to the Americans by the slave traffic. It was known to sailors as Yellow Jack—that much-dreaded and mysterious disease which caused such great loss of life amongst the crews of ships visiting ports in endemic areas. No race is immune; the disease affects all ages and both sexes, though children are less severely affected. In 1900, Carroll

showed that the mosquito vector was *Aedes aegypti*, and that it became infective to man after a period of twelve days provided it was fed on a patient during the first three days of fever; small quantities of blood collected during this period also produced infection on injection into man, and after filtration the serum was still infective. The West African Yellow Fever Commission in 1928 found that Rhesus monkeys (*Macaca mulatta*) were very susceptible to yellow fever, that human sera derived from patients who had suffered from yellow fever protected monkeys, and that the virus would penetrate the intact skin. The virus passes through Berkefeld filters V and N, but not W. Infected blood is very dangerous, and Stokes, Noguchi, Young and others acquired fatal infections in this manner. Many species of mosquito other than *Aedes aegypti* are experimentally capable of transmitting the disease.

It has been shown (14) that the inoculation and subsequent passage of the ordinary viscerotropic virus through the brains of mice converts it into a neurotrophic virus with fixed characters, which can immunise against the viscerotropic virus without producing yellow fever. Subcutaneous injection of immune serum is given before the neurotrophic virus in prophylactic immunisation in man. This is regarded as safe and many have now been immunised. The fact that active immune bodies persist permanently in recovered yellow fever cases has been utilised to determine the endemic incidence of the disease. Mice are used because of the expense of Rhesus monkeys. The protection test (15) consists of an intra-cerebral inoculation of starch solution, followed by an intra-peritoneal injection of serum and virus into mice. If immune bodies be absent from the serum the virus localises in the brain, producing encephalitis and death within fourteen days; if they are present this does not occur. Protection tests afford an index not only of past epidemics but also of acquired immunity following inoculation.

Pathology. The skin and serous membranes may show hæmorrhages and jaundice. Rigor mortis is well marked. The liver is yellow coloured and greasy on section; the gall bladder contains dark, thick bile. Midzonal fatty degeneration and hæmorrhages are frequent and acidophil intra-nuclear inclusion bodies may be present. The kidneys show congestion and cloudy swelling. The heart muscle is pale and flabby; hyaline or granular degeneration of the muscle elements is common and bradycardia due to involvement of the A.V. bundle occurs. Erosions and petechial hæmorrhages involving the stomach and duodenum are frequently found. Death generally occurs on the fifth or sixth day of the disease, by which time the blood has lost its power to infect *via* the skin. The biochemical changes in yellow fever can be mainly interpreted as resulting from loss of liver function and, as its name implies, jaundice is generally present though not necessarily intense. Renal dysfunction is less in evidence. The direct van den Bergh reaction is delayed or biphasic, while a positive indirect varying from 2 to 6 units is generally found. Extreme hypoglycæmia may be encountered before death. Bile pigment and bile salts may appear in the urine which is acid in reaction and contains albumin, copious red cells and casts. In the later stages the blood urea may be increased and occasionally anuria supervenes. The cerebro-spinal fluid is under increased pressure and globulin and chlorides are said to be increased.

Symptoms. The incubation period is from three to five days, though occasionally and in contact infection through the skin it may be as long as ten days. Three clinical types are encountered. 1. *Mild or Larval Types.* These, occurring in epidemics or quiescent periods in endemic areas, are characterised by headache, vomiting and transient fever lasting one to four days. Albuminuria is generally present and mild jaundice may ensue. 2. *Ordinary Type.* Three phases are present: *Sthenic Stage.* The onset is sudden with chill or a rigor, and the temperature rises rapidly to 103° or 104° F. The patient complains of frontal headache, backache, pains in the limbs and photophobia. The

face is flushed, the conjunctivæ injected, the tongue thickly furred with bright-red edges and epigastric pain, nausea and vomiting often ensue. Prostration is severe. Albuminuria occurs on the second day and steadily increases, but bile pigments are not found till later. A rapid, high tension pulse is found at first, but with involvement of the A.V. bundle it slows to 60 to 70 per minute on the third day despite the elevated temperature (Faget's sign); it remains slow during the secondary rise of fever. *Stage of Remission.* This stage is transient and by no means invariably present. It is observed about the third or fourth day, is indicated by a drop in the temperature to 100° F. or lower with amelioration of symptoms, and may terminate in recovery or in recurrence of fever. *Asthenic Stage.* The temperature rises again, but generally does not persist longer than three days. Epigastric discomfort and hiccup may occur. The liver is enlarged and tender and jaundice appears. Petechiæ, melæna and black vomit are not infrequent and there is hypotension and bradycardia. Oliguria

is the rule and anuria may ensue in fatal cases. 3. *Fulminating Type.* This is rapidly fatal and is characterised by high fever, petechial or purpuric skin hæmorrhages, oozing from the gums, epistaxis, black vomit, melæna, jaundice, oliguria and anuria. Severe hiccup, muscular tremor and delirium are marked and the patient dies on the third or fourth day from overwhelming toxæmia.

Relapses are rare, and as a rule the disease does not last more than ten days; once a normal temperature has been reached a steady progress towards recovery ensues. Complications are not common, but boils, abscesses and jaundice may appear during convalescence.

Diagnosis. The mild cases are difficult to recognise. The inoculation into a susceptible animal of blood collected during the first three days of illness or

FIG. 93.—Temperature chart in yellow fever showing the initial pyrexia, remission and secondary rise.

the demonstration by the mouse protection test of immune bodies in the serum during convalescence enables a diagnosis to be made. In cases of average severity, the early albuminuria, excessive prostration, bradycardia and jaundice about the fourth day associated with a tender, enlarged liver, suggest the diagnosis. In both bilious remittent fever and blackwater fever the jaundice is earlier, splenomegaly is marked and malarial parasites may be present. Hæmoglobinuria is of course characteristic of blackwater. Weil's disease is very similar to yellow fever. Clinically, pain and muscular tenderness are more pronounced, Faget's sign is absent, the jaundice is much more severe and there is a history of occupational or other relationship to rats. It was the confusion of Weil's disease with yellow fever in 1918 which led Noguchi erroneously to attribute the cause of the latter disease to a *Leptospira*. In relapsing fever with jaundice there is splenomegaly and spirochætes are readily found in the peripheral blood. In dengue there is no albuminuria; leucopenia with lymphocytosis is characteristic, as is the eruption after the third day; jaundice is rarely if ever observed.

Prognosis. In cases of average severity the mortality rate approximates

to 20 per cent. Many mild unrecognised cases, however, occur in every epidemic and these would lessen the apparent mortality. Deep jaundice, severe hæmorrhages, anuria, intractable hiccup and severe nervous manifestations are of grave import.

Prevention. Cases should be treated in mosquito-proof wards, and anti-mosquito measures instituted. Owing to the danger of direct skin infection, doctors and nurses should use rubber gloves when collecting blood from all febrile cases in endemic areas. Vaccination with neurotrophic virus and immune serum results in the production of immune bodies of high titre in the blood and appears safe, though severe reactions may result. Convalescent serum confers only temporary protection.

Treatment. Absolute rest and skilful nursing are essential. Copious fluids are given, but no food is allowed during the acute phases. Glucose and sodium bicarbonate are added to the drinks or given *per rectum*. In severe cases 1 to 2 pints of intravenous glucose (5 per cent.) may be given daily with benefit. Immune serum does not affect the course of the disease once fever has developed. Symptomatic treatment is often necessary. Cold sponging is indicated where the temperature exceeds 103° F., vomiting may be helped by champagne or tincture of iodine *per os*, hiccup by mustard plaster to the epigastrium, and anuria by cupping to the loins and intravenous glucose injections.

DENGUE

(Break-bone Fever, Dandy Fever)

A specific disease, lasting not more than seven days, caused by a filterable virus which is transmitted by the mosquito *Aedes ægypti*.

Ætiology. Dengue occurs chiefly in tropical countries and to some extent in temperate climates; often it appears in epidemic form but sporadic cases may be encountered. All ages and both sexes are susceptible. The virus is present in the circulating blood during the first three days of fever, and *Aedes ægypti* feeding on such blood become infected for life, though seven to eleven days must elapse before the bite is infective. One attack does not always confer immunity.

Symptoms. The incubation period is three to seven days. The onset is sudden with chilly feelings, headache, aching eyeballs and rapidly developing fever (103° to 104° F.). Excruciating pain is often experienced in the back and around the joints; signs of peri-articular inflammation such as redness and swelling are, however, uncommon. The tongue is furred and red at the margin and the throat and conjunctivæ are congested. Within twenty-four to forty-eight hours the skin over the face, neck and chest not infrequently becomes flushed and reddened—the so-called primary rash. Restlessness and insomnia are characteristic, and anorexia, vomiting and constipation may be present. Enlargement of the cervical and epitrochlear glands are features of some epidemics.

FIG. 94.—Temperature chart in dengue showing the two-phase type of fever.

The pulse, at first accelerated, soon slows and by the third or fourth day there is a critical fall of temperature to 100° F., or lower, accompanied by sweating and occasionally by diarrhoea or epistaxis. The patient often feels better, but after a period, from a few hours to three days, the temperature rises again and the typical saddle-back chart results. Pains in the limbs and mental depression reappear, and a measly or scarlatiniform rash, which fades on pressure, may implicate the limbs and sometimes the trunk. Desquamation and itching may follow. This so-called secondary rash usually appears from the fourth to the sixth day or earlier and lasts from a few hours to three days. A leucopenia with relative lymphocytosis is very characteristic. The secondary bout of fever generally subsides within two or three days and convalescence is as a rule uneventful. Complications are rare, but hyperpyrexia culminating in heat-stroke may supervene in very hot weather. Mental depression, insomnia and troublesome peri-articular joint pains are occasional sequelæ. Epidemics vary considerably in their clinical manifestations, as do individual cases in the same epidemic. Eruptions are by no means always present, pains in the limbs may not be prominent and considerable variation in the type of fever may be encountered. Occasionally the fever is short, lasting only three days (one-phase type); or it may be continuous for six to seven days, but as a rule there is a terminal rise. In the two-phase type the fever is completely interrupted, thus differing from the typical saddle-back chart in which there is no apyrexial period (16). In children, epistaxis and convulsions are more common and the mortality is higher.

Diagnosis. Diagnosis is generally easy during an epidemic; but considerable difficulty may be encountered in differentiating sporadic dengue from sand-fly fever and influenza. The typhus group of fevers and the exanthemata may need consideration, while yellow fever is distinguished by the early albuminuria, profound prostration, jaundice and absence of leucopenia.

Prognosis. The mortality rate is very low, varying from 0.1 to 0.5 per cent. in different epidemics. Deaths are confined to debilitated aged people and young children.

Prevention in dengue consists in the institution of anti-mosquito measures.

Treatment. The patient is kept in bed on a liquid diet. An aperient should be given at the onset and a diaphoretic mixture during the course of the disease. Cold sponging is beneficial where the temperature exceeds 103° F. Aspirin, phenacetin and caffein citrate often relieve the joint pains, but in severe cases morphia may be required. During convalescence a change of climate, liberal diet and tonic treatment are advisable.

SAND-FLY FEVER

(*Phlebotomus Fever, Papataci Fever*)

Sand-fly fever is caused by a filterable virus and transmitted by *Phlebotomus papataci*.

Ætiology. The virus is present in the blood only during the first and second days of the disease, and after the phlebotomus feeds on such blood it cannot transmit the disease until seven days or more have elapsed. This is the period of maturation of the virus in the sand-fly vector which possibly also conveys the virus to its offspring. Sand flies mainly breed under the bark of trees, in the crevices of wood or stony walls and in rockeries, rubbish or rubble surrounding human habitation. The disease occurs either in sporadic form or severe epidemics in tropical and sub-tropical countries; it has also been recorded during the hot weather in temperate climates such as Central Europe. At times 90 per cent. of the population may be affected, people of all ages and both sexes being susceptible. After one attack the immunity is said to be more lasting than in the case of dengue.

Symptoms. The incubation period varies from two to seven days and is generally from three to five days. The onset is sudden with chill, headache, fever and pains in the back and limbs. The face and neck are flushed and the conjunctivæ injected, while vomiting, bradycardia and leucopenia with relative lymphocytosis may occur. Actually the clinical picture is indistinguishable from the primary pyrexia of dengue, but secondary rise of temperature and

FIG. 95.—Temperature chart in Rift Valley fever showing initial pyrexia and two relapses.

rashes are very uncommon. Complications are rare, convalescence rapid, but mental depression may persist for several days after cessation of fever.

Prevention. The disease is best prevented by destroying the insect vector in its breeding places, spraying lower storey rooms with formalin or “Flit” and using a very fine mesh net at night; the ordinary mosquito net will not suffice. The *treatment* is identical with that outlined for dengue which in many respects is closely related to sand-fly fever.

Rift Valley Fever. (*Enzootic Hepatitis*.) This is a specific fever of short duration due to a filterable virus occurring in stock in Kenya Colony (17) and probably other parts of the tropics. Human beings may acquire the infection by direct contact with infected animals or from handling the virus in the laboratory. In man, jaundice is absent. The fever lasts one to three days but relapses may occur. The only recorded fatal human case died with multiple venous thromboses.

CLIMATIC BUBO

(*Tropical Bulbo, Lymphogranuloma Inguinale*)

A venereal disease caused by a filterable virus.

Ætiology. It affects particularly adult males and is contracted in the tropics from native women. Surgeons have contracted axillary buboes from infection of the fingers when operating on these cases. It is found on the east and west coast of Africa, in China and Japan, and an increasing number of cases are now being recognised in England and on the Continent, where it has been transmitted by white women. The pus is bacteria-free and produces large buboes on subcutaneous injection into guinea-pigs. The virus passes through a

Berkefeld filter and can be transmitted to both mice and monkeys on intracerebral injection.

Pathology. The glands are matted together and on section show a reddish tinge; softening and suppuration frequently occur and cavities may be found filled with muco-pus of a greenish or grey colour. Microscopic examination reveals granulomatous tissue composed of fibroblasts, epithelioid cells which often present a palisade arrangement, polymorphonuclear leucocytes and occasionally giant cells.

Symptoms. The incubation period varies from a few days to three weeks, the primary lesion consisting of small herpetiform ulcers on the penis. Unilateral or bilateral swelling of the median group of inguinal glands follows in from one to six weeks' time. Discomfort, tenderness and possibly pain in the groin, accompanied by fever, first direct attention to the condition. The conglomerated glands are slightly tender and very hard to the touch, being covered by skin which is first red and later bluish-violet. As suppuration advances fluctuation is demonstrable and sinuses result in about 50 per cent. of cases. The iliac glands are frequently palpable as a hard mass above Poupart's ligament, but here extensive suppuration never supervenes.

The general features include fever which is generally of remittent type, anorexia and loss of weight; skin eruptions resembling erythema nodosum are described. The temperature may last many weeks or only a few days, while healing of the glands may be complete within two months or be delayed to one and a half years. Other rare conditions found in women, such as chronic elephantiasis and ulceration of the vulva and inflammatory stricture of the rectum, are ascribed to an infection with the same virus; Frei's intradermal test is said to be positive in these cases (18).

Diagnosis. The history of coitus with native women is important. Herpes genitalis resemble the primary lesions, while filarial, septic and tuberculous adenitis, the venereal buboes due to chancroid, gonorrhœa and syphilis, and buboes due to plague, rat-bite fever and tuleræmia may need differentiation. Laboratory investigations including culture and section of material obtained at biopsy and Frei's intradermal test may be of great assistance. The latter is regarded as a specific allergic reaction, and is performed by injecting the sterilised diluted pus into the dermis, observations being made in 48 hours. A reddish infiltrated papule of from 7.5 to 20 mm. diameter is required as positive and indicative of infection with the virus of climatic bubo.

Prognosis. Cases are rarely fatal, but in some instances the disease runs a chronic course and lesions may take eighteen months to heal.

Treatment. The patient is rested in bed and given a nutritious diet and tonic treatment. X-ray irradiation may be applied locally to the bubo. Non-specific protein shock therapy is well worthy of trial and is best given as T.A.B. vaccine, commencing with 50 million and increasing to 300 million bacilli in a series of six graded intravenous injections at intervals of three to four days. Early excision may give excellent results, but the femoral chain of glands should be left intact. Where fluctuation is demonstrable the pus should be aspirated under aseptic conditions, the needle being inserted into healthy skin at some distance from the bubo. Excision at this stage may result in secondary infection.

Diseases due to Rickettsia

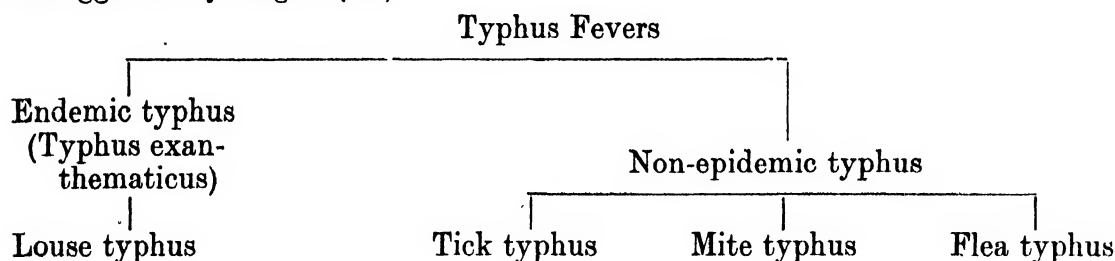

Rickettsia infections only occur in diseases having an arthropod vector and were first described in 1909 by Rickets in Rocky Mountain spotted fever; since then they have been recognised in epidemic typhus, trench fever, Japanese River fever, Brill's disease, tropical typhus affecting man and in heart-water in cattle.

Rickettsia bodies are Gram-negative, bacteria-like organisms of small size

($0.2\ \mu - 0.5\ \mu \times 0.3\ \mu$), showing a marked tendency to pleomorphism. They are found both in the epithelium of the gut and excreta of the arthropod vectors as well as in the blood and endothelial and other cells in human tissues where they have an intracellular location.

The great importance of *Rickettsia* bodies lies in their causal relationship to the rapidly expanding typhus group of fevers. Ordinary typhus is transmitted directly from man to man by lice, while the non-epidemic forms are primarily diseases of rodents, being transmitted to man by fleas, ticks and mites.

The classification of this group is at present best based on the insect vector as suggested by Megaw (19).

The Weil-Felix Reaction (20). This serological reaction is of considerable value in recognising both the epidemic and the non-epidemic forms of typhus, and depends on the fact that certain coliform organisms of the *Proteus* group are agglutinated by the sera of typhus patients. Two strains of organism are now being used, *B. proteus* X19 and *B. proteus* XK; agglutination reactions of 1/100 are diagnostic and generally become evident during the second week of the disease. The titre may rise as high as 1/30,000 during convalescence and the reaction may remain positive for several months. A strong positive reaction to X19 suggests louse or flea typhus and a strong positive to XK favours mite typhus, while a negative or weak response to both strains fourteen days from the onset of a typhus-like fever supports the diagnosis of tick typhus.

تیفوس

LOUSE TYPHUS

(*Endemic Typhus* ; *Typhus Exanthematicus* ; Jail Fever)

Typhus fever is a louse-borne disease occurring in epidemic form and probably caused by *Rickettsia prowazeki*.

Ætiology. This is the only form of typhus which occurs in epidemic form, and until 1837 it was not differentiated from typhoid fever. It was not uncommon last century in England, Scotland and Wales; it is now no longer encountered. During the Great War there were extensive outbreaks in Russia and Germany. It may occur at any time in the colder climates of Europe or during the cool weather in hot countries such as Egypt and Palestine; in India it is only found in the Himalayas and in North-West plains, but not further South in the tropics proper, as lice do not survive such heat. There is no racial immunity, people of any age may be attacked and one attack generally confers immunity. Filthy surroundings, over-crowding, under-feeding and famine conditions favour its spread. Human blood collected during the febrile period is infective to monkeys, but the infective agent does not pass through Berkefeld filters. Nicolle and Conseil demonstrated the transmission of typhus by infected lice, but it is probable that human infection actually takes place by the rubbing of the excreta through abrasions in the skin rather than directly by biting. Lice become infected five to ten days after feeding on typhus blood and once infected remain so for life; in the epithelial cells lining their alimentary tract *Rickettsia prowazeki* is found. *Rickettsia* is also demonstrable in the endothelial cells of the smaller blood vessels in human cases.

Pathology. The spleen is soft and possibly enlarged in the early stages,

while the liver and kidneys show cloudy swelling and the heart muscle is degenerated. Broncho-pneumonia is not infrequently terminal. The characteristic lesions which were described by Fraenkel in 1914 consist of proliferation of the endothelial lining of the arterial and capillary walls, followed by necrosis and perhaps perivascular infiltration with lymphocytes and plasma cells. Typhus pseudo-tubercles are thus produced and may be found in the skin, viscera and brain, where they especially involve the basal ganglia, medulla and cortex. Thrombosis of the smaller skin vessels accounts for the petechial eruption.

Symptoms. The incubation period is generally from eight to twelve days, the extremes being five to twenty days. Prodromata include general malaise, nausea and anorexia. The onset is frequently sudden with chilly feelings or shivering, fever, frontal headache, pains in the back and limbs, and, more rarely, vomiting and epigastric pain. Drowsiness and apathy are marked even early

FIG. 96.—Temperature chart in louse typhus showing continuous fever with fall by crisis on the thirteenth day.

in the disease. The mentality is dulled, the face is flushed, the conjunctivæ congested and the tongue coated; constipation is marked. The temperature usually reaches its fastigium about the third day, and for the next eight to twelve days continuous fever is the rule (Chart IV.). Then remissions occur, and the temperature finally reaches normal by rapid lysis or crisis some twelve to sixteen days from the onset. Occasionally the temperature is of remittent type from an early stage in the disease. About the fourth or fifth day the rash appears as a rose-red macular or papular eruption which at first fades on pressure, but later frequently becomes petechial. It is often first seen in the axillæ and loins and later involves the whole trunk and generally the legs and arms, but not the face. In fulminating cases purpuric patches appear. The rash itself lasts a variable period from several days to two weeks. Toxic manifestations become established early and stupor may give place to a typhoid state with or without delirium as early as the fifth day; symptoms of meningismus with neck retraction may be superadded and simulate meningitis. As the disease progresses the tongue dries and sometimes becomes black in colour, sordes develops on the teeth, the pulse becomes more rapid and weak, cardiac sounds are distant

and the blood pressure low. Myocardial failure may supervene, while cough accompanied by moist sounds at the bases of the lungs are not infrequent during the second week. Constipation is a marked feature of the disease, but diarrhoea occasionally replaces it in severe cases.

Laboratory investigations may be of value. Little change is noted in the red cell count, but a mild leucocytosis with neutrophilia is not infrequent. The cerebro-spinal fluid is under increased pressure and shows an excess of lymphocytes and globulin. Most important of all, during the second week the serum almost invariably agglutinates *B. proteus* X19.

Complications are by no means infrequent and include bronchitis, broncho-pneumonia, thrombophlebitis of the femoral and other veins, arterial thromboses with gangrene of the extremities, particularly of the toes and feet, parotitis, otitis media, deafness and bed sores.

Diagnosis. During epidemics little difficulty is experienced, while in sporadic cases the stigmata of intoxication, the temperature chart and the rash will suggest the diagnosis which should receive serological confirmation later.

Prognosis. The death rate, which varies in different epidemics from 10 to 30 per cent., is particularly high in the aged and low in children. An early typhoidal state, a purpuric eruption and complications like broncho-pneumonia and thrombosis are of serious significance.

Prevention consists in the destruction of body lice and preventing skin contact with these infected arthropods.

Treatment. The patient must be nursed in the recumbent position and allowed plenty of fresh air and fluids. Particular care should be taken of the hygiene of the mouth, constipation should be controlled by enemata and bed sores prevented. A fluid diet including fruit juices, glucose, milk and broths should be administered and the fluid intake reinforced where necessary by nutrient enemata and intravenous glucose solution (5 per cent.). Cool sponging is advisable both to lower the temperature and for sleeplessness and other nervous manifestations; brandy and sedatives like morphia, chloral and hyoscine may also be necessary. The withdrawal of cerebro-spinal fluid by lumbar puncture may relieve the meningismus and is a rational procedure, while in adults convalescent serum should be given if available.

Tick Typhus. The best known form of tick typhus is Rocky Mountain or spotted fever which occurs in North America, but other typhus-like fevers transmitted by ticks are encountered in India, South Africa, Kenya, Nigeria and the Mediterranean coast. The Weil-Felix agglutination reaction does not appear to be of the same value in this group of diseases, as it is so frequently negative or only positive in low titre.

ROCKY MOUNTAIN FEVER

(*Spotted Fever ; Black Fever ; Blue Disease*)

The disease has a limited geographical distribution in Northern America, mainly occurring in the Rocky Mountain regions at 3,000 to 4,000 feet. The infective agent is a Rickettsia organism (*Derma-centroxenus rickettsi*) which has been found in infected ticks of the species *Derma-centor andersoni* or *venustus* as well as in infected human beings. The natural hosts are wild rodents, including ground and mountain squirrels and chipmunks. The disease can be experimentally inoculated into guinea-pigs which give a positive Pinkerton-Mooser reaction characterised by septicaemia, orchitis and an effusion into the tunica vaginalis containing Rickettsia bodies. One attack of the disease confers immunity, but not to louse typhus.

Pathology. The morbid anatomy is similar to louse typhus, but proliferation of vascular epithelium more often leads to thrombosis and gangrene.

Symptoms. The incubation period varies from four to twelve days, and the

general course and clinical picture is similar to louse typhus. The rash, however, is more conspicuous and appears from the second to the fifth day on the wrists, ankles and back, subsequently extending to the face, palms and soles, which is not the case in louse typhus. The spleen also is commonly enlarged, epistaxis and jaundice are not infrequent, while the fever tends to be more prolonged, and to show more conspicuous remissions during the fastigium; often an intermittent type of fever develops a few days before lysis. Early albuminuria and a leucocytosis with an increase in monocytes are found.

Gangrene of the scrotum, prepuce, fingers, toes and tonsils may occur even in mild cases; broncho-pneumonia is less frequent than in louse typhus, but otherwise the complications are similar in the two diseases.

Diagnosis. The diagnosis may be confirmed by a positive Pinkerton-Mooser reaction in an inoculated guinea-pig. The Weil-Felix reaction to X19 and XK is at most only weakly positive. Cerebro-spinal fever may be differentiated by examination of the spinal fluid.

Prognosis. The mortality varies markedly in different regions.

Treatment. The avoidance of tick bites in infected regions and cauterisation with carbolic acid when they are known to occur are the best prophylactic measures. Medicinal treatment follows the lines outlined for louse typhus.

TICK TYPHUS IN INDIA

A fever of the typhus group resembling Rocky Mountain fever in many respects and probably transmitted from wild rodents by ticks.

Ætiology. The disease is endemic in the central plateau of India in the cold season at a height of 1,500 feet and in the Himalayas at an altitude of 4,000 feet during the summer and autumn. Most of the recorded cases have been in Europeans. The usual vector appears to be *Rhipicephalus sanguineus* (21), but this has not been proved.

Symptoms. The incubation period is generally seven to twelve days. There is the usual rapid onset with a step-like rise in temperature and fever lasting ten to sixteen days; the rash appears on the third to the fifth day and consists of rose-red macules or papules fading on pressure. As with other forms of typhus the spits become dark red, then brown and then no longer fade on pressure; brown staining may persist for some weeks. The arms and legs are first involved and subsequently the palms and soles as well as the trunk and face. Petechiæ and purpuric eruptions may be encountered. Nervous prostration is marked, but jaundice is rare. The Weil-Felix is negative or only slightly positive (1/80 to 1/100) to proteus X19; there is a moderate leucocytosis with increase in the mononuclears, but unlike Rocky Mountain fever, guinea-pigs do not appear susceptible to experimental inoculation.

Diagnosis. The occurrence of a typhus-like fever in endemic areas will suggest the diagnosis.

Prognosis. The disease is less severe than Rocky Mountain fever, the probable mortality being about 5 per cent.

Treatment. This is similar to that outlined for louse typhus.

Mite Typhus. Originally the type of typhus fever known as tsutsugamushi or Japanese River fever, transmitted by the bite of larval mites, was thought to have a geographical distribution restricted to certain rivers in Northern Japan, but later it was found in Formosa and Korea. It is now known to occur in other places in the Far East, including the Federated Malay States and Sumatra, and probably in China and Australia as well. Not all cases of mite typhus, however, conform to the clinical picture of Japanese River fever, and probably there are a number of different though allied diseases in this group. For example, in the scrub typhus of Malay no primary sore or lymphangitis is encountered, while the pseudo-typhus of Sumatra has a much lower mortality

rate ; in addition, both these diseases are transmitted by the *Trombicula deliensis*, whereas in Japanese River fever the arthropod vector is *Trombicula akumushi*.

JAPANESE RIVER FEVER

(*Tsutsugamushi* ; *Kedani Mite Disease* ; *Flood Fever* ; *Akumushi Disease*)

This disease affects both sexes of all ages and is particularly common in hemp harvesters in the island of Nippon, in Japan, in Korea and Formosa. *Rickettsia nipponica* is the probable cause and is transmitted by the larval mite *Trombicula akumushi*, which often attaches itself to the skin for two or three days ; local necrosis and ulceration ensue, followed by tender enlargement of the related lymphatic glands.

Pathology. Myocardial softening, pulmonary congestion, bronchitis and splenomegaly, in addition to local ulcers and adenitis, have been described.

Symptoms. Some five to fourteen days after a mite bite the patient develops a shiver associated with headache, giddiness and fever which is at first of continuous and later of remittent type, lasting two to three weeks. Locally, a small ulcer is found associated with a dark areola, lymphangitis and tender enlargement of the corresponding lymph glands. The rash appears from the fifth to the seventh day and consists of red macules and papules about 0.5 cm. in diameter. The arms, legs, trunk, face, palms and soles may all be involved. Petechiæ rarely, if ever, occur. The spleen may be enlarged and the usual cardiac, pulmonary and nervous manifestations common to the typhus group of fevers occur. There is a leucopenia associated with a decrease in the neutrophils, and the Weil-Felix reaction is strongly positive to *B. proteus* XK but not to X19.

Prognosis. The mortality varies from 5 to 60 per cent. in different areas.

Treatment. The destruction of field rodents, and the prevention of mite bites by suitable clothing, daily bathing and the removal of mites are important preventive measures. Medical treatment follows the lines outlined for louse typhus.

Flea Typhus. There are two main recognised types of typhus transmitted by fleas—Brills' disease in the United States of America, and the urban form of tropical typhus in Malaya affecting people working in stores ; the reservoir of infection is probably the rat in both instances and the vector the rat flea, *Xenopsylla cheopis*. The sera in both diseases give strongly positive Weil-Felix agglutination reactions to *B. proteus* X19.

Both are non-epidemic in type, while clinically they are allied to mild cases of louse typhus, the mortality is low and does not exceed 2 per cent. In Brills' disease there is a rapid onset of continuous fever with a maculo-papular eruption about the fifth day, which rarely if ever becomes purpuric ; the fever terminates by crisis about the fourteenth day. Frontal headache, apathy and prostration are marked as in louse typhus.

Nicolle regards marine typhus occurring in the crews of French warships as being transmitted by rat fleas from infected rats, and Megaw points out that certain of the typhus-like fevers occurring along the Mediterranean coast and in the Far East and Australia may ultimately be found to fall into this category.

Bacterial Diseases

A number of bacterial diseases occurring commonly in the tropics are also found in Europe, and one important group, the enteric fevers which include typhoid and the paratyphoid fevers, has been dealt with in another section (p. 71).

BACILLARY DYSENTERY

Bacillary dysentery is an acute specific colitis caused by various dysentery bacilli which can be isolated from the stools.

Ætiology. The organisms causing dysentery are the Shiga-Kruse bacillus

isolated in 1897, which does not ferment mannite, and the mannite-fermenting Flexner Y bacilli, of which there are five serological strains known as V, W, X, Y and Z. In addition there is Sonne's bacillus which is a late lactose fermenter.

All ages, races and both sexes are susceptible, but the disease is much more frequently encountered in the tropics and sub-tropics than in temperate climates. Outbreaks of Flexner dysentery, however, do occur from time to time in military barracks, prisons and asylums in Europe, and organisms of this type are responsible for many cases of summer diarrhoea in children. The mode of spread is by faecal contamination of food and water from an infected individual or by house-flies. Overcrowding, deficient diet and malnutrition predispose to infection. In the tropics its greater incidence is in the early summer, autumn and the rainy season. During the South African War the troops were decimated with this disease, and in the Eastern theatres of the World War, dysentery in epidemic form occurred, as in Gallipoli, with serious consequences.

Pathology. In bacillary dysentery there is an acute fibrinous colitis, the rectum, sigmoid flexure and caecum being most intensely involved, while in the most severe cases the lower 2 or 3 feet of the ileum may also be implicated. The liver is congested and enlarged, the mesenteric glands reddened and swollen and emaciation marked. Outstanding features are the superficial nature of the inflammation and the fact that the mucous membrane is uniformly involved. At first, the mucosa appears red and congested; sometimes it shows petechial hæmorrhages and is often covered with muco-sanguineous exudate; in acute fulminating Shiga infections large areas of colonic mucosa may be rapidly converted into a green, gangrenous membrane. As the inflammation progresses the mucosa becomes infiltrated with fibrin and a patchy coagulation necrosis results; exfoliation produces transverse or irregular, serpiginous ulcers situated for the most part on the swollen mucosal folds, which are separated by thickened, oedematous, congested mucous membrane. When recovery ensues healing takes place without scarring. Occasionally cases of chronic dysentery have been described showing thickening and rigidity of the bowel wall and a granular bleeding mucosa with isolated ulcers. Such a condition is indistinguishable from chronic ulcerative colitis of temperate climates which a minority opinion also attributes to infection with dysentery bacilli.

Symptoms. The clinical features vary within wide limits according to the resistance of the patient and the virulence and type of the causative organism. Some infections are often mild, Flexner Y of moderate severity, and Shiga most grave. As in cholera, toxæmia and dehydration may each play an important rôle in the production of the clinical picture.

The *typical* case presents a sudden onset with fever, possibly preceded by a chill and generally followed by headache, nausea and vomiting. Colicky abdominal pain, the frequent passage of small, muco-sanguineous stools and tenesmus due to sphincteric spasm are characteristic. The bowels may be open four to fifty times in the twenty-four hours and Manson's descriptive phase, "glued to the commode," not inappropriately describes the condition. As toxæmia increases, the cheeks become flushed, the expression anxious, the fever greater, the pulse more rapid and the tongue coated and yellow. Restlessness, mental confusion, sleeplessness and delirium may develop. With dehydration there is an increase in these nervous symptoms associated with thirst, pinched features, sunken eyes, a dry brown tongue, oliguria, urea retention, collapse of the peripheral veins, muscular cramps, a feeble, rapid pulse and low blood pressure, and in infants depression of the fontanelles. Where acidosis develops the breathing becomes deeper, more rapid and even irregular. The severest cases may simulate cholera and die in a state of collapse with sub-normal temperature, shrivelled skin and cold, blue extremities. Mild catarrhal cases, on the other hand, may be afebrile and be mistaken for simple diarrhoea, culture being necessary to demonstrate the true nature of the infection.

The appearance of the *stools* varies with the severity and stage of the disease. Early, they may be of fluid consistency, brownish or brownish-red in colour and soon contain glassy mucus ; alternatively they may be frankly muco-sanguineous from onset. Later they become muco-purulent and only as the inflammation subsides do they assume fæculent characters ; finally, solid stools with a mucous coating are passed. Microscopic examination shows that the exudate contains red blood corpuscles, numerous polymorphonuclear leucocytes, desquamated columnar epithelial cells and large macrophage cells which resemble non-motile amœbæ and are often mistaken for *E. histolytica*.

If cultures are to be successful, specimens must be collected as soon after the onset of fever as possible. Martin and Williams (22) found that 68 per cent. were positive when specimens were examined within the first five days of the disease, 17·4 per cent. in the second five days, and only 6·3 per cent. in the third five-day period. Furthermore, stools sent to the laboratory for investigation must contain mucus, for it is from such exudate that the bacilli are cultured ; finally, the specimen must be absolutely fresh and uncontaminated by urine or antiseptic, otherwise growth is impeded or impossible.

Examination of the patient in the early stages may reveal rigidity of the abdominal muscles, but localised pain and tenderness are infrequent owing to the absence of peritoneal involvement. Later the contracted sigmoid may be palpable. The temperature is remittent at first and sometimes intermittent subsequently, but with proper treatment generally subsides within seven to fourteen days. Continued fever implies persisting infection, either with dysenteric organisms or secondary invaders.

In *entero-dysentery*, where the small intestine is involved, the rectum and sigmoid may escape ; in these circumstances tenesmus is absent and the stools are not so typically colonic in type. The onset is sudden, toxic features, including vomiting, are marked ; the temperature is high, the mouth covered with sordes, while a typhoidal state may rapidly supervene. In the most severe cases choleraic-like stools are passed and the patient may die quite early with collapse symptoms.

Complications. Since the dysentery bacilli only invade the superficial lining of the gut, local complications such as perforation and stricture are not encountered ; septicæmia rarely, if ever, occurs, and hæmoculture is negative. A toxic arthritis involving the large joints such as knees, ankles, elbows, shoulders and wrists is not infrequent ; it takes the form of effusions into the joints and peri-arthritis, and especially occurs during convalescence from Shiga infections. Its onset, which is generally within the first three or four weeks, may be longer delayed ; it lasts a variable time, but rarely leads to permanent deformity. The aspirated fluid is almost invariably sterile on culture, though in very rare cases Shiga bacilli have been isolated. Acute conjunctivitis, iridocyclitis and iritis are also uncommon. They are of toxic origin and usually clear up without leaving any permanent damage. Parotitis, bronchial pneumonia, and multiple neuritis are rarer complications and terminal intussusception has been recorded in children.

Course. Fulminating cases die rapidly from toxæmia and dehydration, but in the absence of complications and with appropriate treatment ordinary cases become afebrile in two weeks. Occasionally, however, cases last two or even three months with remittent or intermittent fever, sweating, marked colonic distension and frequent muco-purulent stools ; intense weakness and emaciation develop, death ensuing from toxæmia and intercurrent disease. In other instances the disease becomes chronic, but as a general rule the natural tendency in all types of bacillary dysentery which are properly treated is towards complete recovery without any permanent structural alteration in the colon. Irritable colon is a not infrequent sequela of bacillary dysentery, and this is largely responsible for the misconception that chronic dysentery is a common disease.

Chronic Dysentery. When bacillary dysentery becomes chronic there is almost invariably a history of neglect on the part of the patient or of lack of appropriate treatment. In these circumstances the bowels act more frequently than usual, are foul smelling, generally contain mucus and pus and sometimes blood. Afebrile intermissions may occur in which the stools are normal, but generally mucoid stools persist and the patient does not feel he has made a complete recovery. Febrile exacerbations with frequent dysenteric stools recur, and in the later stages emaciation, anæmia, trophic changes in the skin and œdema of the feet develop. The abdomen becomes scaphoid and the colon palpably thickened and tender; bed sores and intercurrent infections like pneumonia are liable to develop. Dysentery bacilli are isolated with difficulty, Cunningham (23) being successful in only 26·7 per cent. of his Indian cases. In many respects the remittent type closely resembles chronic ulcerative colitis of temperate climates, but the ætiological relationship of the latter disease to the Flexner Y. group of organisms is far from proven, and much work needs to be done on both these diseases before they can be regarded as identical.

Diagnosis. Little difficulty is experienced in diagnosing severe Shiga cases, though one type may simulate cholera. Trouble may arise with *Flexner Y* and *Sonne infections*, and these may need to be differentiated by laboratory methods from amoebic, bilharzial and ciliate dysentery, though an acute onset with fever, marked urgency of bowel symptoms and frequent mucoid stools containing bright blood support the diagnosis of bacillary dysentery. Carcinoma of the pelvic colon may cause confusion in chronic cases and sigmoidoscopy or X-ray examination after a barium enema may become necessary for their differentiation.

Sigmoidoscopy is rarely indicated in the acute stages when the bowel shows a uniformly diffuse reddening and hyperæmia associated with white or greenish necrotic membrane and muco-sanguineous exudate. Later, as the membrane separates, superficial serpiginous ulcers more or less transversely situated on the mucosal folds may be observed surrounded by acutely inflamed mucous membrane. In chronic dysentery these ulcers are said to persist and deepen and the mucosa to be largely replaced by granulation tissue showing a red, hyperæmic, granular surface, bleeding readily on instrumentation. The bowel walls then become rigid and spastic, the sigmoidoscopic picture resembling that of idiopathic ulcerative colitis of temperate climates. The history of onset during an epidemic is suggestive, and the isolation of dysentery organisms from the mucoid stools during the acute or later stages will establish the diagnosis.

Prognosis. Shiga dysentery is a very serious disease, and prompt treatment with anti-dysenteric serum and measures to combat dehydration are necessary to save life. Healthy adults with Flexner dysentery generally recover, but children, the ill-nourished and the aged not infrequently succumb.

Prevention. As the disease is spread by contamination of food and water by infected individuals and flies, similar measures to those adopted in enteric fever should be instituted. Prophylactic vaccination has unfortunately not proved successful.

Treatment. Treatment is directed to resting the bowel by a low residue diet and combating toxæmia and dehydration. Good nursing, continuous bed rest and warmth in a cold climate are essential. A preliminary dose of oleum ricini ($\frac{1}{2}$ ounce) with tinct. opii (15 minims) should be given, followed by sodium sulphate (1 drachm) given at first two-hourly, then three-hourly and finally four-hourly as the stools improve and until they become fæulent. Only boiled water is permitted for the first twenty-four to forty-eight hours, then lactose, glucose and albumin and barley water followed by meat juice, clear soups, jellies and sprulac. Arrowroot and sago puddings are given later, but milk is never well borne and is contra-indicated. Specific anti-dysenteric serum should be given at once in doses of 80 to 120 c.c.—especially in Shiga infections—

and this decision must be made immediately on the clinical aspects of the case and the naked eye and microscopic features of the stools. When circumstances permit, the patient should be tested for hypersensitivity to horse serum, and, if positive, desensitisation with small initial doses carried out. In toxic cases, gentle colonic lavage with 1 to 2 pints of saline (0.85 per cent.) and bicarbonate (1.5 per cent.) may be used to reinforce the action of sodium sulphate in relieving intestinal toxæmia. Fluid loss must be combated by intravenous injections of glucose (5 per cent.) or hypertonic saline solution as in cholera. Symptomatic treatment includes turpentine stupes and hot fomentations to the abdomen, morphine ($\frac{1}{8}$ gr.) and tinct. opii (15 minims) for griping, and opium and starch enemas for tenesmus. Gaseous distension of the abdomen may be relieved by giving adsorbents like animal charcoal and kaolin by mouth.

Chronic Dysentery. A high calorie, high vitamin, low residue diet is advisable. Rectal lavage with the following solutions are worthy of trial: saline (0.85 per cent.), bicarbonate (1.5 per cent.), yatren (1 in 40), tannic acid (1 per cent.), potassium permanganate (1 in 5,000), etc. Daily injections of 4 to 8 ounces of a 5 per cent. suspension of bismuth subgallate in olive oil, if tolerated, may prove beneficial. Specific treatment in the form of anti-dysenteric serum is not as effective as in acute dysentery. Appendicostomy permits colonic lavage from the cæcum, and cæcostomy or ileostomy affords rest for the large bowel. Operation should, however, only be undertaken in intractable cases where all other measures have failed. Iron in adequate dosage and blood transfusion are of great benefit if anæmia be present, and acid hydrochl. dil. B.P. (1 drachm) should be given thrice daily after food where acid secretion is defective.

CHOLERA

Cholera is an acute specific disease of the small intestine due to Koch's comma vibrio.

Ætiology. Cholera has been endemic in India for many centuries, and epidemics arise in the spring and summer mainly through the movements of pilgrims. Occasional outbreaks have occurred in Asia, Europe and America since 1817. The *Vibrio comma* or *Vibrio cholerae*, which was first discovered in Egypt by Koch in 1883 (24), is passed in the stools of carriers, and in this way infects food and water. Flies also disseminate the disease by fouling food, such as sweetmeats and milk, with infected fæces. All races, both sexes, and individuals of all ages are susceptible. Generally cholera vibrios disappear from the stools of convalescents within five days, and only 7 per cent. of patients remain carriers for more than ten days after an attack. Persistent carriers are very rare, but occasionally healthy contacts become carriers without having suffered any bowel disturbance. Though vibrios exist in great numbers in the small intestines, they are not demonstrable in blood cultures. They have been found in limited numbers in consolidated areas in the lungs and other internal organs and have a special predilection for the gall-bladder which may be inflamed. Soluble exotoxins and endotoxins are produced by the vibrios, but only low titre anti-sera have to date been produced by animal inoculations.

Pathology. Rigor mortis sets in early. On opening the abdomen the small intestines are found shrunken and collapsed, the mucous membrane is intensely congested and may show petechial hæmorrhages. Enlargement of the lymphoid follicles in the ileum may also be present. The liver is congested and the gall-bladder distended with viscid, thick bile. The spleen is shrunken and the lungs collapsed and dry. The kidneys are swollen and congested, sometimes showing minute hæmorrhages, while the blood is viscous and tarry. The stools rapidly assume their "rice-water" appearance and several quarts may be passed in a few hours. The fluid is neutral or slightly alkaline in reaction with a specific gravity of 1,006–1,013, and contains sodium chloride, albumin and

mucin. On standing it deposits a finely granular, greyish-white sediment consisting of epithelium, leucocytes, shreds of tissue, crystals of ammonium-magnesium phosphate, blood corpuscles and vibrios. The absence of colour is due to dilution and to the fact that the bile becomes viscous like treacle and cannot be expelled from the gall-bladder. In consequence bile pigment does not reach the duodenum and the normal fæcal pigment, stercobilin, is not produced in the intestine. There is increased viscosity of the blood, the specific gravity increasing from the normal 1,056–1,058 to 1,063 or more; biochemical analysis shows reduced blood chloride, decreased plasma CO_2 , and urea and phosphate retention. Hæmatocrit investigations reveal a plasma loss of over 35 per cent. in mild and 64 per cent. in severe cases and a polycythæmia of from 6 to 8 million red cells per c.mm. results. Marked leucocytosis is also common, the counts varying from 15,000 to 50,000 per c.mm. The urine is markedly decreased in quantity, and contains albumin and casts. Anuria may rapidly supervene from inability of the heart to maintain the renal circulation owing to decreased blood volume and the increased viscosity of the blood.

Symptoms. *Onset.* The incubation period is generally two to five days. During an epidemic individual cases may show considerable variation in their severity and clinical manifestations, though the majority of them (95 per cent.) conform to the type known as *cholera gravis*. Here the onset is usually sudden, and in a few hours the stools lose their fæculent character and come to resemble "rice-water." Some authorities describe an initial phase lasting twenty-four hours in which there is looseness of the bowels, colic, headache, vomiting and mental depression, but this is not characteristic of the Indian epidemics.

Collapse or Algid Stage. Following the initial purging, which is accompanied by borborygmi but by little colicky pain, vomiting first of food and later of "whey-like" fluid commences. The patient suffers from thirst, the tongue, which was at first coated and white, becomes dry and the epigastrium tender. Painful muscular cramps appear in the legs; the temperature becomes markedly subnormal and the collapse or algid stage, due to fluid and chloride loss and tissue dehydration, sets in. The face is pinched, the skin cold, blue and shrunken, the eyes sunken and the breath loses its warmth. The axillary temperature falls 4° or 5° F. below normal. The pulse, from 90 to 100 per minute, is small, thready and almost imperceptible, the respirations are short and quick—from 35 to 40 per minute. There is profound muscular prostration, but the patient restlessly throws his limbs about in purposeless fashion. The voice is harsh, or may be lowered to a whisper (*vox cholERICA*), or the lips only may move in a mumbled attempt to speak. The systolic blood pressure falls to 50 to 70 mm., while the peripheral veins are collapsed and urinary secretion diminishes or ceases altogether for thirty-six to forty-eight hours. Generally the patient retains complete consciousness though lying apathetic and indifferent except when aroused by painful muscular cramps. This stage, which begins six to seven hours after the first symptoms, generally lasts twelve to twenty-four hours, and is succeeded by the stage of reaction unless the patient dies without rallying.

Stage of Reaction. There is a gradual rise in the skin and mouth temperatures, and a general improvement in the circulation with increase in the blood pressure and urinary output. Restlessness and cramps disappear, the skin gradually regains its natural colour and loses its shrunken appearance, the conjunctivæ are injected and congested patches of dusky redness appear on the face. If the circulation be restored the only danger is that absorption of cholera toxin may lead to hyperpyrexia and death. On the other hand, if the circulation be inadequate to restore renal function, anuria will persist and uræmia result. Should the stage of reaction go on to recovery, convalescence is often slow and may be delayed by complications.

Clinical Varieties. Mild or *ambulatory* cases may occur in which the

disease does not pass beyond a stage of diarrhœa, but vibrios are nevertheless present and such patients act as carriers during an epidemic. A more severe form, *choleraic diarrhœa*, begins suddenly with abundant yellowish-brown fluid stools containing epithelium, associated with borborygmi and cramps in the calves, and may last from a few days to one or two weeks. *Cholerine* is a still nearer approach to *cholera gravis*: the onset is sudden, vomiting accompanies the purging and the fæculent stools may gradually become colourless; cramps, cooling of the extremities, scanty urine with albumin and casts appear. Recovery is slow. In *cholera sicca* the stage of collapse sets in immediately, and the patient dies before purging commences, though at autopsy there is abundance of watery stools in the alimentary canal.

Complications and Sequelæ. Cardiac failure may occur in convalescence after slight exertion, and parotitis, nephritis, broncho-pneumonia and enteritis may call for special treatment. Before the introduction of intravenous injections for dehydration, sloughing of the cornea and gangrene of the fingers, toes and genitals were commonly enough encountered. Abortion and premature delivery are not infrequent in severe cases.

Diagnosis. Little difficulty arises during an epidemic, but in atypical or sporadic cases isolation of the *Vibrio cholerae* is essential. The differential diagnosis includes the choleraic forms of heat-stroke, malaria and bacillary dysentery, cholera *nostras*, ptomaine, arsenic and perchloride of mercury poisoning, the early stages of trichiniasis infestation and poisoning by certain mushroom-like fungi. *Cholera sicca* may prove indistinguishable from meningitis until lumbar puncture is performed; muscular rigidity, retraction of the abdomen and a positive Kernig's sign may be present in both diseases.

Prognosis. Cholera is exceedingly fatal in the very young and the aged, and in pregnant, debilitated or alcoholic subjects. Unfavourable features include prolonged collapse with excessive sweating, prostration, cyanosis, absence of pulse at the wrist and markedly sub-normal temperatures; cardiovascular failure, uræmia and hyperpyrexia are of grave significance. Oliguria after the collapsed stage, especially if associated with much albumin, casts and a low urea excretion, is unfavourable and careful urinary measurement should always be made. Where modern treatment cannot be applied, the mortality varies from 40 to 60 per cent., and is greater at the beginning of the epidemic than towards the end. On the other hand, if cases be treated in hospital with modern methods, the mortality is reduced to approximately 11 per cent. (25).

Prevention. During epidemics injections of cholera vaccine should be given as they afford temporary immunity for a period of about six months. Unboiled milk, uncooked food, salads, raw fruit and unboiled water must be rigidly avoided. Houses should be fly-proof, all food must be covered, and drinking and eating utensils washed in boiling water and dried by heat. Purgatives should be avoided during epidemics as this may predispose to infection and even the mildest gastro-intestinal disturbance should receive careful attention.

Treatment. The patient is practically starved for the first few days and kept strictly at bed rest; only boiled water, barley water and glucose are allowed. Kaolin given in a strength of 1 in 3 in water has been given in almost unlimited amounts with the idea of adsorbing cholera toxin. Calcium permanganate pills, 2 grains, every quarter of an hour for eight doses, then half-hourly, may be administered with the object of destroying it. In the absence of high titre cholera anti-sera, the basis of treatment consists of replacing fluid and salts lost from the body by the copious diarrhœa and vomiting. Intravenous injections should be given whenever the specific gravity of the blood rises to 1.063 or over. A systolic blood pressure of 70 mm. or less, especially if associated with cramps, cold extremities, restlessness and cyanosis, is an indication for transfusion. Rogers (25) advises two solutions, the first being a hypertonic saline, consisting

of sodium chloride, 120 grains, and calcium chloride, 4 grains, to the pint of sterile distilled water; this replaces fluid and chloride loss. The second is an alkaline solution consisting of sodium chloride, 90 grains, and sodium bicarbonate, 160 grains, to the pint of distilled water; this tends to counteract acidosis and uræmia. In order to avoid conversion of the bicarbonate into the toxic carbonate, the solution is sterilised by filtration through a Seitz asbestos filter, or the specially purified bicarbonate is added just before use to sterile normal saline. During the stage of copious evacuations, each time the patient requires an injection 1 pint of the alkaline solution is given followed by 1 to 3 pints of the hypertonic saline according to requirements. A specific gravity of 1,062 indicates that 2 pints are required; 1,063, 3 pints; 1,064, 4 pints, with the object of keeping the specific gravity below 1,060. Injections may need to be repeated. The rectal temperature must be considered as well as the specific gravity of the blood, for fatal hyperpyrexia may result when hot injections are given to an unconscious patient with a high temperature. This deadly complication occurs when the rectal temperature is 102° F. or higher; if it be 101° F. the solution for intravenous injection must not be warmer than 80° F., *i.e.*, room temperature in the tropics.

In the reaction stage when the temperature rises and circulation is restored, the patient must be closely watched for hyperpyrexia, and cold sponging must be started as soon as the temperature reaches 103·5° F. Threatened uræmia is best treated by hot applications and dry cupping to the loins, and by alkaline solutions given both *per rectum* and intravenously; these are repeated when necessary every few hours until 40 ounces of urine are passed in the twenty-four hours. Intravenous injections of 5 per cent. glucose may also prove helpful. Patients must be kept recumbent in bed for several days to avoid sudden cardiac failure, and, until the kidneys act freely, only junket and farinaceous foods like cornflour and arrowroot should be allowed lest relapse occur. Bacteriophage has been used both in the prevention and treatment of cholera, but at present its value is uncertain.

LEPROSY

(*Lepra* : *Elephantiasis Græcorum*)

A chronic disease of low infectivity peculiar to man, caused by *Mycobacterium lepræ* or *Bacillus lepræ* and characterised by nodular lesions of the skin and mucous membranes (nodular type) and involvement of the nerves (anæsthetic type).

Ætiology. Leprosy has a widespread geographical distribution occurring, amongst other places, in India, Burma, Siam, China, Japan, parts of Africa, Central America and South America, the West Indies, Mexico and Oceania. In Europe it is common only in Norway. Individuals of either sex and any race and age may acquire the infection. Children are the most susceptible, but the disease is rarely contracted in infancy and is definitely not hereditary. *Mycobacterium lepræ* was discovered in the tissues of lepers in 1874 by Hansen (26); it is non-motile and acid-fast, but has never been cultivated on artificial media or successfully inoculated into animals. The bacilli occur in great numbers in skin lepromata, septal ulcers and nasal mucus and less profusely in the implicated nerves. The mode of spread is unknown, but intimate contact with infective cases is essential.

Pathology. Leprosy bacilli spread through the lymphatics of the corium and subcutaneous tissue, producing skin granulomata and involvement of the lymph glands. Three stages are described: (1) a quiescent phase in which the bacilli multiply in the papillary lymph spaces, secreting a glutinous substance and causing loss of skin pigment; (2) a reactionary phase characterised by inflammation with swelling of the skin and disappearance of the glutinous matrix and dissemination of the bacilli and toxins through the blood stream with more general involvement of the corium and also the nerve trunks; microscopically,

large multinuclear lepra cells may be seen; (3) a stage of resolution when the erythema disappears, fibrosis occurs and the skin looks thin and wrinkled. The mucous membranes of the nose, mouth and larynx, the eye, and internal organs like the liver, lungs and the testicles may be involved in advanced cases; the viscera contain numerous bacilli and may undergo lardaceous degeneration. When the nerves are attacked they swell from proliferation of cells in the sheath, become reddish-grey in colour and undergo an axonal degeneration in association with which the anterior horn cells may be affected. Scanty bacilli are demonstrable in the endoneurium and perineurium. Anæsthesia, paresis, paralysis, muscular wasting, deformity and trophic ulcers follow.

Symptoms. The incubation period varies from six months to five years, and often the bacilli remain latent for long periods until some factor such as intercurrent disease precipitates clinical manifestations. There are three main types of the disease: (1) nodular leprosy; (2) anæsthetic or nerve leprosy; (3) mixed leprosy.

(1) *Nodular Leprosy.* Prodromal manifestations include leprotic fever, sweating, shivering, muscular weakness, gastro-intestinal disturbances, especially diarrhœa, alternating dryness and excessive secretion of nasal mucus and epistaxis. The first skin lesions appear as slightly raised erythematous macules (lepra maculosa) which later on show dissociation of sensation and absence of sweating; the face, buttocks, legs and arms are especially involved, and after the primary exanthem has disappeared a brownish discoloration of the skin may result. With a fresh eruption fever reappears and bacilli may be found in the blood. Simultaneously with the eruption, or more frequently after one or two recurrences, reddish-brown elastic nodules appear (lepra tuberculosa) which tend to become more generalised; the dorsal and not the palmar surfaces of the hands and feet are affected, while in size they vary from a small pea to a hazel nut. On the face they produce great thickening of the tissues over the forehead and of the nose, cheeks and lobes of the ears, the countenance acquiring a leonine expression (leontiasis). Hair tends to be lost, especially over the outer third of the eyebrows, the nipples become hypertrophied, while the mucous membrane of the mouth, gums, nose, pharynx and larynx may be affected with nodules, which may disappear, remain stationary or ulcerate. Blindness, dysphagia and vocal changes may result, while tendons and bones may be eroded and joints opened. Secondary anæmia and debility are found in advanced cases.

(2) *Anæsthetic Leprosy.* Prodromata include mental depression, chilliness, malaise, neuralgic pains and paræsthesia, such as burning or tingling which involve especially the facial, ulnar and perineal nerves. Numbness of the hands and feet, anæsthesia of ulnar type and anæsthetic patches somewhat resembling ringworm are early features. Often these anæsthetic patches which have commenced as erythematous, pigmented or depigmented areas become smooth, dry and hairless. After a time the ulnar, perineal and great auricular nerves become palpably thickened and wasting of the hypothenar eminence associated with contraction of the third and fourth fingers appears. Paralysis with atrophy especially involving the interossei of the hands and feet and the muscles of the forearm follow, and claw hand, wrist and foot drop result. Perforating ulcers are common and necrosis or absorption of the small bones with disappearance of fingers and toes ensues, the wounds healing up with remarkable completeness (lepra mutilans). Sometimes the fifth and seventh cranial nerves are implicated and ectropion of the lower lid complicated by corneal ulceration may occur.

(3) *Mixed Leprosy.* Cases in which nerve and skin lesions co-exist are common, but there is a tendency for nerve lesions to show themselves when the skin lesions are disappearing, and *vice versa*.

Symptoms depend on the stage of the disease. In the quiescent phase the patient may feel quite well and be able to carry on his work satisfactorily; in

the reactionary phase there will be malaise and fever, while in the phase of resolution healing occurs which implies the establishment of a certain degree of immunity.

Course and Complications. The disease generally runs a chronic course with exacerbations and remissions extending over many years, though, where the resistance is low, nodular leprosy may run a rapid, febrile course with widespread skin lesions. The majority of cases die of intercurrent infections like pulmonary tuberculosis, nephritis, dysentery, pneumonia, sepsis with pyæmia and gangrene or local involvement of the larynx with obstruction and pulmonary complications.

Diagnosis. In nodular leprosy the differential diagnosis includes lupus vulgaris, skin tuberculosis, syphilis, yaws, dermal leishmaniasis, molluscum fibrosum and sarcomatosis. In nerve leprosy with ulnar involvement, syringomyelia, Morvan's disease (analgesic whitlow), progressive muscular atrophy, peripheral neuritis and cervical rib call for consideration. In other cases, leucoderma, psoriasis, scleroderma, Raynaud's disease, and even ainhum, may cause confusion. In nodular leprosy clumps of acid-fast bacilli are readily found in nasal mucus, in scrapings of nasal ulcers made under direct vision, using a speculum, and in the serous exudate from nodules and skin granulomata scraped with a scalpel. Smears prepared from the under surface of a piece of skin snipped with curved forceps from the lobe of the ear are valuable in diagnosis, and gland puncture may also reveal bacilli.

In nerve leprosy the earliest skin lesions differ from patches of leucoderma in being anæsthetic to light touch, less extensive and less symmetrically distributed (27). Adjacent nerves may be thickened, but lepra bacilli, as a rule, cannot be demonstrated unless a portion of the implicated nerve be excised and examined; the nasal mucus is free from bacilli and diagnosis in such cases has generally to be made on clinical grounds.

Prognosis. This largely depends on the type of the disease and the stage at which the case comes under treatment. Nodular leprosy is generally more serious than anæsthetic, and febrile cases showing widespread, rapidly extending lesions or successive crops of nodules may run a progressively fatal course, despite treatment. Relapses are common and cure is frequently more apparent than real; a guarded prognosis should therefore be given even in early cases. It is very important to keep all patients under observation for at least two years after they have been rendered bacilli-free and after active symptoms have ceased.

Prevention. Compulsory segregation has largely failed owing to the concealment of early cases, and this is particularly unfortunate as modern treatment yields its best results in this stage. Rogers advocates that early cases not yet discharging bacilli should be treated as out-patients in hospitals and dispensaries, and that advanced infective cases should be isolated as far as possible on a voluntary basis by making leper colonies attractive and efficient. When bacilli free, patients should be released and examined periodically to see that they remain so. Children of lepers must be isolated from the parents from birth and brought up separately, and contacts who have lived in the same house as lepers should be bacteriologically examined every few months for five years.

Treatment. It is essential to increase the general resistance by nourishing food, fresh air, regulated exercise and cheerful surroundings. Intercurrent disease must be treated. The sedimentation test is widely used as a guide to treatment; slow sedimentation is favourable, but a high sedimentation rate indicates active infection and contra-indicates drug treatment. Only when the general health is satisfactory and the resistance is high should special drugs be used, otherwise lepra reactions may occur with increase in the local lesions, and even bacillæmia in nodular cases, and agonising pain in anæsthetic leprosy.

Various drugs, including preparations of chaulmoogra and hydnocarpus oil,

their ethyl esters and sodium salts have been used. They should not be given in the active second stage in which the infiltrated and thickened tissues swarm with lepra bacilli. Improvement in early cases may be expected in three or four months, while lesions may have cleared in six to twelve months, but in advanced cases one to two years may be required (27).

Chaulmoogra oil by the mouth, commencing with 20 minims t.d.s. and gradually increased until 1 to 2 drachms are administered in the twenty-four hours. Fresh hydnocarpus oil is administered orally in enteric-coated capsules to prevent nausea, and mixed with 4 per cent. creosote to prevent pain if given as an injection. Antileprol, which is a mixture of the ethyl esters of unsaturated acids of chaulmoogra oil, is administered after food in capsules of 1 gramme, the dosage being 1 to 3 grammes daily. Moogrol (ethyl chaulmoograte) is injected weekly into the muscles, beginning with 1 c.c. and increasing the dose every third week until a maximum of 6 c.c. is attained.

Sodium gynocardate can be given by the mouth (12 grains t.d.s.) or as an intramuscular or intravenous injection. Sodium hydnocarpate (alepol) is the more active preparation; 1 to 5 c.c. of a 3 per cent. solution of "alepol" is almost painless, rapidly absorbed and efficient either by subcutaneous or intramuscular injection. For intravenous use a 1 per cent. solution is used.

Recently Muir has been using a special preparation of ethyl esters of hydnocarpus with 4 per cent. creosote injected intradermally. From 0.03 c.c. to 0.06 c.c. is injected at each puncture, as many as 100 punctures being required to inject 5 c.c. The process is painful and time-consuming, and six months may be required to infiltrate all the affected skin.

When lepra reactions occur, hot drinks, an aspirin-phenacetin-caffein nitrate mixture, large doses of alkalies and calcium salts should be administered. Protein shock and small doses of tartar emetic (0.02 to 0.04 gramme daily) may also help. In nerve leprosy the agonising pain may be relieved by ephedrine sulphate ($\frac{1}{2}$ grain) orally, or injections of adrenalin.

Vapour baths, diathermy and surgical stretching of the nerves are useful in nerve cases, and periarterial sympathectomy may assist the healing of trophic ulcers of the feet. Various drugs, including ichthyol, pyrogallie acid, resorcin and chrysarobin, are used in treating the skin lesions, while ultra-violet light is of value in increasing the general resistance.

Melioidosis. This very fatal disease, caused by *Pfeifferella whitmorei*, is found in Burma, British Malaya, Ceylon and Cochin China; it resembles glanders, and was first described in man by Whitmore in 1913 (28), and was named melioidosis by Stanton and Fletcher in 1921 (29). Melioidosis is a disease of rodents, but the exact method by which man acquires it is not understood. *B. whitmorei*, which is a bipolar staining organism, is readily cultivated from the blood or nodules, but it is not easy to demonstrate in pus.

Pathology. The internal organs, including the liver, spleen, lungs, intestine and kidneys, may show small caseous nodules which sometimes coalesce to form large honeycombed abscesses. Pustules and bullæ may implicate the skin.

Symptoms. The clinical picture varies within considerable limits. In the most acute cases of septicæmia there is a short burst of fever associated with severe vomiting, diarrhoea and collapse which may resemble cholera in its intensity and kill in a few days. In other cases remittent or intermittent fever may last for weeks or even months before death occurs.

Diagnosis. The clinical types may resemble plague, broncho-pneumonia, typhoid, malaria, liver abscess, infective endocarditis, generalised tuberculosis and pyelitis (30). Should melioidosis be suspected clinically, search for the organism in the blood, sputum, urine, cerebro-spinal fluid or pus aspirated from the spleen or liver must be made.

Treatment. The disease in man is almost invariably fatal; but autogenous vaccines are worth a trial.

PLAGUE*(Oriental Plague ; Black Death ; Pestis)*

In the Middle Ages *plague* was used to designate any severe or fatal epidemic, but now its meaning is restricted to one particular disease, caused by *Bacillus pestis* and primarily implicating rodents (31) and conveyed to man by rat fleas.

Ætiology. The first great epidemic in Europe, the plague of Justinian, occurred in the sixth century, but since 1665, when it devastated London, European epidemics have gradually become less frequent. In 1894 an outbreak occurred in Hong Kong and South-Eastern China ; in 1896 the disease spread to Bombay and other parts of India, when it caused 7 million deaths during the next fifteen years. Since then it has occasionally appeared in different parts of Europe, South Africa and Central and South America. It is now most common in India, Thibet, Uganda and Mesopotamia. Less important centres are Siberia, California, South and tropical Africa. High temperature with a dry atmosphere, *i.e.*, a high saturation deficiency, kills the flea vector, so that fewer cases occur during the hot weather in countries like India. Any person may be affected.

The plague bacillus, *Bacillus pestis* or *Pasteurella pestis*, was isolated from a plague bubo in 1894 at Hong Kong. It is a short, flagellated, Gram-negative rod with bi-polar staining, measuring 1.0 to 1.5 μ in length, and is readily cultivated on artificial media. Guinea-pigs and other laboratory animals are susceptible. In rats, both acute and chronic forms of plague are encountered, and either the large grey or sewer rat (*Rattus norvegicus*) or the smaller and more domesticated black species (*Rattus rattus*) may be affected. Field rats and other rodents, such as ground squirrels, shrews, gerbilles and mice, may be responsible for outbreaks ; a species of marmot, the "tarabagan" (*Arctomys bobac*), caused the Manchurian epidemic of pneumonic plague in the winter of 1910-11.

The rat flea, *Xenopsylla cheopsis*, acts as an excellent incubator for plague bacilli, and when it sucks up infected blood the bacilli proliferate rapidly, growing right forward and mechanically blocking the proventriculus, so that blood cannot get through into the stomach. Bacot and Martin (32) found that the starving anthropod, on biting another host, regurgitates bacilli back into the wound made by its jaws and so spreads the infection. Pneumonic plague in contradistinction to the bubonic variety is intensely infectious, being directly transmitted by droplet spray infection from person to person ; nurses and doctors frequently acquired the disease during the Manchurian epidemic.

Morbid Anatomy. A primary vesicle is only occasionally found at the site of entry of plague bacilli, while the adjacent chain of lymph glands is acutely inflamed (primary bubo). There is intense congestion and hæmorrhage, with peri-glandular, gelatinous œdema and matting together of adjacent glands ; those more distantly situated are greyish-red and congested. Septicæmia is almost invariable in severe cases, and in the most fulminating type evidence of primary bubo may be lacking. Toxins from the *B. pestis* damage the capillary endothelium and produce congestion and hæmorrhages in the mucous and serous membranes and the skin. The heart muscle, liver and kidneys are congested with cloudy-swelling and fatty change, while the spleen is enlarged, hyperæmic or hæmorrhagic. The brain and meninges show congestion and petechiæ.

Pneumonic plague appears to start as a broncho-pneumonia, but later the whole lobe may be implicated. Congestion of the bronchial mucosa, pleural ecchymoses and adenitis of the bronchial glands are common findings.

Symptoms. The incubation period generally varies from two to five days, but may be prolonged to ten days. Several types are differentiated clinically. (1) *Bubonic Plague.* The disease may be heralded by lassitude, headache, backache, vertigo and shivering, followed by a rapid rise of temperature. Indefinable fear, absent-mindedness, staggering gait and tremulous speech

are not infrequently present as well as nausea, vomiting and diarrhoea. The pulse rate increases to 100 to 130 and the temperature to 103° to 104° F.; occasionally in severe cases it reaches 107° F. The tongue, at first moist and white, soon becomes dry and brown and a typhoid condition may supervene with delirium and coma, sordes on the lips and teeth, failing pulse and cold extremities. The urine is scanty, acid, highly coloured and contains albumin, while oliguria may be replaced by suppression in fatal cases. On the second or third day the local signs of the primary bubo appear in the glands draining the infected bite. The femoral or inguinal glands are implicated in 70 per cent., the axillary group in 20 per cent., and the submaxillary and cervical in 10 per cent. of cases. The glands rapidly swell to the size of a hen's egg or larger, become extremely tender and painful and suppurate if the patient survives the first week. Death generally takes place from the third to the sixth day, and may be preceded by petechial or subcutaneous hæmorrhages, epistaxis, hæmoptysis, hæmatemesis and melæna. During the second week convalescence is generally established, but it may be prolonged by suppurative adenitis or boils and carbuncles involving the buttock, lower extremities or neck. Occasionally fever persists for weeks or even months. (2) *Septicæmic Plague*. The patient is struck down with great rapidity. There is frontal headache, fever, vomiting, delirium and coma associated with splenomegaly and slight general enlargement of the lymph glands. The pyrexia may be only slight, and bleeding into the skin and the mucous membranes occurs with a rapidly fatal termination within twenty-four to forty-eight hours on onset. Diagnosis is made by a positive blood culture. Fulminant cases (*Pestis siderans*) are included in this category. (3) *Pneumonic Plague*. This variety was first recognised in Bombay in 1896. Its onset is with a rigor and the symptoms resemble bubonic plague, but respiratory features become urgent in a day or two and dominate the picture. There is pain and tightness in the chest, dyspnoea, cyanosis, cough, expectoration of a profuse, blood-stained watery sputum teeming with plague bacilli. Râles, crepitations and possibly, near the end, areas of diminished vesicular murmur and resonance are found. Cardiac failure is common, and death occurs almost invariably within four days and generally before definite signs of consolidation are demonstrable. (4) *Intestinal Plague*. This type, which was encountered by Wilm in the Hong Kong epidemic of 1896, is very rare. It is characterised by nausea, vomiting, incessant purging of offensive, bile-stained, liquid stools, often containing blood. Pathological lesions are present in the intestine. (5) *Cerebral Plague*. The mental features so characteristic of ordinary bubonic plague are accentuated, and delirium, fits and coma rapidly supervene; in some respects the condition resembles cerebral malaria. A fatal plague meningitis with cytological exudate and plague bacilli in the cerebro-spinal fluid may also occur. (6) *Cellulo-cutaneous Plague*. In this variety carbuncles appear, having a necrosed ulcerated centre, an indurated edge and surrounding erythema which may be studded with vesicles. Culture reveals the presence of *B. pestis*. (7) *Abortive or Ambulatory Plague (Pestis minor)*. Here the fever is so slight and the general features so mild that the patient does not take to bed. The lymph glands merely swell and become tender, or if they suppurate they resolve without serious indisposition.

• **Complications.** The ordinary severe bubonic case may develop a fatal septicæmia or pneumonia during the first few days, while in the second week septic complications, including parotitis, boils, carbuncles, cellulitis and broncho-pneumonia may complicate convalescence. Sometimes the buboes become indolent and fail to heal for weeks.

Diagnosis. Early in the epidemic difficulty may be experienced; apart from adenitis, those clinical features of special importance are mental dullness, hesitating speech and a staggering gait somewhat suggestive of alcoholism. Plague buboes have to be differentiated from climatic bubo, chancroid or syphilitic

bubo, septic adenitis, the adenitis of rat-bite fever and possibly tularæmia. Puncture of the gland reveals bipolar bacilli in smears and culture; the latter is best done by injecting a little sterile saline into the bubo or painful area, subsequently aspirating and culturing the contents of the syringe on agar slopes. A crucial test is the transmission of plague to the white rat by smearing infected material on its skin. Septicæmic plague is diagnosed by positive blood culture, 0.25 c.c. of blood being run on to each agar slope, which in the tropics is subsequently incubated at room temperature.

In pneumonic plague herpes is absent, and the sputum, which is watery and contains bright blood, is not viscid and rusty as in pneumonia; microscopic examinations immediately reveal *B. pestis* in large numbers.

Prognosis. The mortality in bubonic plague is much lower in Europeans (25 to 30 per cent.) than in natives (75 to 80 per cent.). Axillary buboes are less favourable than inguinal, while cervical buboes are specially dangerous owing to the danger of asphyxia. Positive blood cultures are of serious significance and only the mildest septicæmias recover. Liston found that cases showing more than 20 organisms per c.mm. of blood invariably died. Pneumonic plague is always fatal.

Prevention. Wherever possible, rats and fleas should be destroyed and measures taken to prevent contact with man. The building of rat-proof granaries and houses, the evacuation of infected villages and huts during an epidemic, systemic destruction by poisoning and trapping, the fumigation of ships and their protection against rat invasion while in port are measures useful in controlling the spread of plague. Prophylactic inoculation with Haffkine's vaccine is important; 4 c.c. are injected subcutaneously and, though severe reactions follow, immunity lasting from half to one year is established with a single large injection. In Europeans multiple injections with smaller doses can be substituted with benefit.

Treatment. Good nursing, absolute rest in bed and liquid diet are essential. Anti-plague serum, if available, should be given in full dosage intravenously at the earliest possible moment (33). Cardiac tonics and intravenous glucose solution (5 per cent.) should be given early. Hyperpyrexia calls for prompt treatment. Hot fomentations, antiphlogistine or belladonna and glycerine may be applied to the buboes, and early incision made when suppuration occurs. Morphia may be necessary for the relief of pain.

UNDULANT FEVER

(*Malta Fever; Mediterranean Fever; Abortus Fever, etc.*)

This is a prolonged fever with many intermissions and a tendency to relapse; splenomegaly, sweating, anæmia, painful swelling of the joints and neuritis are features of the disease. It may be caused by *Brucella melitensis* conveyed in goats' milk, or by *Brucella abortus*, of which there are bovine and porcine strains.

Ætiology. Malta fever, which is primarily a disease of goats, is endemic in the Mediterranean basin, and human cases have been recorded from the Red Sea littoral, South Africa, India, China, the West Indies, parts of South Africa, the Mississippi valley and elsewhere. All ages and both sexes are liable. In Malta the disease was most common in the second and third decades, and especially in the dry summer months of July and August. The Maltese appeared less susceptible than garrison troops. Bruce (34) in 1887 discovered the organism, *Brucella melitensis*, in the spleen of patients dying of the disease, cultured it successfully and experimentally reproduced the disease in monkeys. It is a small cocco-bacillus which causes a generalised septicæmia, and may be recovered from the blood, bile, fæces, milk and urine. Zammit in 1905 found *Br. melitensis* in the blood of goats and showed that their sera agglutinated the organism.

Specific agglutinins also appear in the milk, which, though containing numerous organisms, may be of good quality.

Other varieties include *Brucella abortus* of Bang, discovered in 1897 (35), which causes contagious abortion of cattle and swine and may produce a disease in man indistinguishable from Malta fever. The organism is excreted in the udder of cows, and man may become infected by ingesting infected milk, butter or cheese, in handling the carcasses of infected swine or cattle, or by contact with their excreta. Cases are recorded from Southern Rhodesia, where Bevan in 1922 first suggested its relationship to epizootic abortion of cattle, also from South Africa, the United States of America and Europe, etc. The disease is being recognised with increasing frequency in England.

Pathology. There is enlargement and congestion of the liver, marked hypertrophy of the spleen, an increase in pericardial fluid, patchy areas of con-

FIG. 97.—Temperature in a Case of Malta Fever of Undulant Type.

gestion in the intestinal mucosa and submucosa and enlargement of the mesenteric glands which may break down and contain semi-purulent matrix.

Symptoms. The incubation period is about fourteen days and the onset generally insidious. Symptoms include pyrexia, headache, pains in the joints, sleeplessness, thirst, furred tongue, loss of appetite and weight, nausea and tenderness in the epigastric region. The bowels are usually constipated, the spleen is generally enlarged and often tender and painful; sometimes there is hepatomegaly, while profuse perspirations occur, perhaps associated with sudamina. Anæmia is often marked and the red corpuscles may fall to below 3,000,000 per c.mm. In about half the cases the joints become red, swollen and painful, and the *Brucella* organisms may be isolated from the effused fluid. Neuritis is common; it may involve the sciatic or facial nerve, beginning acutely and persisting for a long time in a less intense form. Albuminuria may be present during the acute stages. The headache and severer symptoms may subside in two or three weeks, but the pyrexia often continues for six or nine months and only slowly subsides. The temperature is not necessarily continuously high throughout this period, but may have wavy exacerbations of two or three weeks' duration followed by intervals of lower or normal temperature for a fortnight

or longer (*undulant* type, Fig. 97), but there are several other clinical varieties. (1) *Ambulatory type*. Here symptoms are so slight that the person continues his ordinary occupation; insignificant symptoms with transient fever may develop and rapidly disappear, the serum tests alone revealing infection. Shaw, in Malta, found that 79 out of 525 dock hands at work in Malta gave positive agglutination reactions, when 22 of these positive cases were proved carriers, since *Brucella* organisms were detected either in the blood or urine or both. (2) *Malignant type*. The patient is suddenly attacked with severe fever, joint pains, vomiting and diarrhoea; cardiac weakness and a typhoidal state frequently develop and broncho-pneumonia may supervene. Death generally takes place from the twentieth to the thirtieth day with hyperpyrexia, temperatures of 106° to 108° F. being recorded. (3) *Intermittent type*. A sudden afternoon rise to 105° F. or higher, associated with chilly feelings or definite rigor develops. Pyrexia terminates with drenching sweats, and the condition can only be differentiated from malaria fever by the absence of parasites. (4) *Continuous type*. There is a uniform fever extending over a period of from four to twelve weeks. Clinically, many cases of abortus fever are typical of the undulant type, but the continuous and intermittent types are perhaps more common.

Complications. The more important include bronchitis, broncho-pneumonia, neuritis, arthritis with effusion, parotitis, orchitis, purpura and suppurative osteitis. In females there may be menorrhagia, abortion, premature labour and mastitis, while children are liable to meningo-encephalitis.

Diagnosis. The diseases liable to be confused with undulant fever include enteric fever, acute rheumatism, tuberculosis, septicæmia, subacute bacterial endocarditis, malaria, kala-azar, amœbic abscess of the liver, occult pyogenic infections and pulmonary lymph-adenoma associated with the Pel-Ebstein syndrome. Early in the disease hæmoculture is the most satisfactory method of diagnosis, and demonstrable septicæmia may last for several months. Liver infusion broth is a good culture medium, but *Br. abortus* must be grown in an atmosphere of 10 per cent. carbon dioxide, or, better still, 1·0 c.c. of suspected blood should be inoculated into the peritoneal cavity of a guinea-pig and cultures subsequently made from the peritoneal cavity in about a week's time, or from the spleen at a later date. With both *Br. melitensis* and *Br. abortus* it is necessary to incubate for at least a fortnight before reporting a negative result. Macroscopic agglutination reactions are of great diagnostic value; dead emulsions of *Br. melitensis* and *Br. abortus* should both be used as antigens. Absorption of agglutinin may be necessary to distinguish the two infections. Agglutinin appears from about the twelfth day onwards, and an ascending series of dilutions of from 1 in 50 to 1 in 10,000 should be employed. Where low titre agglutinations are obtained (1 in 100) the reaction should be repeated in a week's time to ascertain if the titre is rising. The complement fixation test is also valuable, and may be positive in the later stages when the agglutination reaction has become negative. Burnett's intradermal test is performed by injecting 0·05 to 0·1 c.c. of the filtrate of a twenty days' broth culture into the skin of the arm; the reaction, which becomes positive within six hours and lasts one to two days, consists of a round or oval area of infiltration of about 0·5 cm. diameter. It is said to be positive from the seventh to the tenth day of fever and to persist for ten months after recovery.

Prognosis. The mortality rate varies from 2 to 6 per cent. but it is higher in young children and people over forty owing to secondary infection (36). Death generally results, with hyperpyrexia during the first three weeks of fever in the malignant types, but at any time a fatal recrudescence may occur associated with cardiac failure, broncho-pneumonia or a toxæmic, typhoid state.

Prevention. The prohibition of the consumption of goats' milk and cream and cheese made from it is advisable, or failing this, boiling the milk renders it safe. Infected animals should be killed off and goats should only be bred from

sound stock. In cases of *Br. abortus* infection, prohibition of the use of infected cow's milk and avoidance of contact with the carcasses or excreta of infected bovines or porcines are advisable. In handling *Brucella* cultures laboratory workers must be exceedingly careful, as infection is rapidly acquired in a fashion which is at present not fully understood; *Br. abortus* infects through the intact skin of guinea-pigs.

Treatment. In so prolonged a fever, careful nursing and a nourishing diet adequate in vitamin-containing foods are desirable and these include sufficient milk, eggs, fish, milk puddings, orange juice, tomato juice and yeast. Vaccines are of doubtful value and the results of specific anti-serum treatment, though promising, are not yet convincing. Specific protein therapy in the form of intravenous injections of T.A.B. vaccine, commencing with 50 millions and working up to 250 millions at three-day intervals, may cure. Various symptoms and complications should be treated as they arise and whenever the temperature exceeds 103° F. cold sponging is indicated.

TULARÆMIA

(*Deer-fly Fever*; *Pahvant Valley Fever*; *Rabbit Fever*)

This is a septicæmic condition resembling bubonic plague, due to *Brucella tularensis* (*Bacterium tularense*), which occurs particularly in rodents. Man appears to be generally infected from handling diseased animals or working with the organisms. Cases have been reported from the United States, Japan, Siberia and Norway.

Ætiology. McCoy, in 1911 (37), met with a plague-like disease in ground-squirrels (*Citellus beecheyi*), and in the following year in association with Chapin (38) he isolated the causative organism, *Br. tularensis*, which was a small Gram-negative bacillus ($0.3 \times 0.2 \mu$). The disease affects rodents in the Western States of America, especially ground-squirrels and jack-rabbits, and is spread by ticks. *Br. tularensis* can pass through the intact skin and in this way butchers and poultrymen may be infected with the glandular type of the disease. Laboratory workers may contract it by droplet-spray infection with anæsthetising infected animals or in handling cultures.

Pathology. In man there is suppurative adenitis of the local lymph glands which break down and ulcerate, or generalised signs of septicæmia with involvement of the spleen, lungs and liver.

Symptoms. There are two types of infection: (1) the *bubonic* type which is usually seen in butchers and poultrymen, with an acute onset with headache, shivering or rigors, pains in the limbs and fever. In these cases a papule is generally present, particularly on the back of the hands, and this breaks down, leaving a ragged ulcer. An acute lymph-adenitis follows with involvement of the epitrochlear and axillary glands; these become swollen and painful and later may adhere to the skin and discharge pus. The average period of fever is twenty-six days and the mean duration of the disease five and a quarter months (Foshay). In chronic cases symptoms may persist for over a year. Sometimes the organism attacks the conjunctiva; ulcers form on the inner surface of the eyelids and swelling and tenderness of the preauricular and cervical glands follow. (2) The *typhoidal* type which particularly affects laboratory workers, characterised by fever, chills, sweats, headache, pains in the joints, malaise and no localising features; the temperature may subside within three weeks, but sometimes irregular fever may continue for many months (39), the condition resembling undulant fever and typhoid.

Diagnosis. The occupational history, especially in people handling rabbits in endemic areas, should arouse suspicion, but the final court of appeal is the laboratory. The agglutination reaction is of very definite value, for during the first week the serum fails to agglutinate *Br. tularensis* at 1 in 20 dilutions, while in the second week a rise in titre occurs, reaching a maximum of 1 in 600

to 1 in 1,000 from the fourth to the seventh week. There is a steady decline during subsequent months, a titre of 1 in 100 to 1 in 50 generally being encountered at the end of the year. Guinea-pigs injected with the purulent discharge of the organism develop characteristic lesions. Foshay (40) has recently introduced a special diagnostic skin test which enables a diagnosis to be made during the first week of the disease.

Prognosis. In laboratory workers the disease is not generally fatal; in the bubonic type the mortality is about 10 to 20 per cent. if untreated.

Treatment. An anti-serum which has been successfully prepared from goats and horses recently, is given intravenously in a dosage of 15 c.c. on two successive days (41) (Foshay) as a rule; by its use the duration of the disease has been shortened by 50 per cent.

OROYA FEVER

(Carrion's Disease)

This disease, caused by *Bartonella bacilliformis*, has a peculiar geographical distribution, being confined to valleys between 3,000 to 9,000 feet on the western slopes of the Peruvian Andes. In 1885, Carrion inoculated himself with material from a verruga nodule and died of Oroya fever one month later. An attack of either disease confers immunity to both. Barton in 1909 found small rod-like organisms in the erythrocytes in Oroya fever. In 1926, Noguchi and Battistini cultured the organism on artificial media and successfully infected monkeys (42); the less resistant developed a disease resembling Oroya fever, while the more resistant showed only verruga-like nodules. Noguchi infected Rhesus monkeys with emulsion of sand-flies from Peru, and subsequently demonstrated *Bartonella bacilliformis* in the blood; two species, *Phlebotomus verrucarum* and *Phlebotomus noguchi*, are regarded as possible vectors.

Pathology. The skin shows petechiæ and a yellowish waxy tinting, the heart is flabby, presenting features of fatty degeneration, while the liver is enlarged, showing areas of zonal necrosis. The lymph glands are swollen and œdematous, the enlarged spleen contains multiple infarcts, and a yellow, granular pigment deposited in the endothelial and splenic cells which fails to give the prussian blue reaction. Red megaloblastic marrow fills the long bones, and ecchymoses often involve the serous sacs. *Bartonella bacilliformis* is found in the reticulo-endothelial cells as well as in the red corpuscles.

Symptoms. About three weeks after visiting an endemic area, malaise, headache and irregular remittent fever appear associated with joint pains and tenderness over the long bones and sternum. The spleen becomes enlarged and palpable, the lymph glands swollen and a hæmolytic megalocytic anæmia with hyperbilirubinæmia rapidly develops. In severe cases the red cell count falls as low as 1,000,000 to 2,000,000 per c.mm. The colour index often exceeds 1.0, while a leucocytosis associated with immature neutrophils and metamyelocytes is commonly encountered. Breathlessness, palpitation, cardiac murmurs, œdema of the legs and retinal hæmorrhages, skin petechiæ and oozing of blood from the gums develop; not infrequently severe cases lapse into coma and die with a subnormal temperature. Verruga nodules may appear during convalescence.

Diagnosis. A febrile hæmolytic anæmia of megalocytic type associated with tender bones and a history of recent residence in the Andes should suggest the diagnosis. The high leucocytosis and the presence of metamyelocytes differentiates the blood picture from pernicious anæmia in which there is leukopœnia, lymphocytosis and a neutrophile shift to the right. *Bartonella bacilliformis* is only demonstrated in blood smears in severe cases.

Prognosis. The mortality rate varies from 30 to 40 per cent.

Treatment. Repeated blood transfusions are indicated for severe anæmia, and salvarsan is stated to have been used with success in some cases. Liver extract does not appear to be effective.

Verruga Peruana. This is now regarded as the eruptive stage of Oroya fever in patients with a high resistance to *Bartonella bacilliformis* infection. Noguchi has successfully transmitted verruga nodules by local inoculations from monkey to monkey, and subsequently cultured *Bartonella bacilliformis* from the local lesions. Splenectomised or specially susceptible monkeys may develop systemic manifestations resembling Oroya fever.

Pathology. Verruga nodules consist of vascular granulation tissue showing a marked tendency to ulceration and hæmorrhage. Microscopic examination shows proliferation of the endothelial lining of capillaries and lymphatics, plasma cells and fibroblasts in a delicate vascular reticulum.

Symptoms. From two to three weeks after exposure, fever and severe pains develop in the knees, ankles and wrists, but a few days after the eruption appears the temperature falls to normal. Two types of skin lesions are seen. (1) *The miliary type* involves the face and exterior surfaces of the limbs and sometimes the conjunctivæ and mucous membranes of the nose and pharynx. Pink macules appear which deepen in colour and assume a nodular appearance. These nodules are flat, smooth and either flattened or pedunculated; they bleed readily and heal without scarring. (2) *The nodular type* of eruption develops more slowly but attains larger dimensions and may form ulcerated fungating granulomata, the size of a walnut, which bleed profusely. The eruption comes in crops, involves the flexures of the medium-sized joints and lasts for two to three months.

Diagnosis. This is generally straightforward, especially considering the local geographical distribution of the disease. Secondary yaws, molluscum, contagiosum, Dercum's disease, multiple angiomata and fibro-sarcomata may need differentiation.

Prognosis. This is good, the chief danger being hæmorrhage in the nodular type and secondary respiratory infection with the miliary type involving mucous membranes. In children the disease runs a mild course.

Treatment. Skin lesions should be dressed aseptically, and fungating nodules excised under local anæsthesia to prevent hæmorrhage. Blood transfusion and iron therapy are indicated in cases of severe blood loss.

TROPICAL MYOSITIS

(*Tropical pyomyositis* ; *Myositis purulenta tropica*)

This disease, characterised by acute painful swellings of muscles with or without pus formation, has a widespread tropical distribution. It may affect people of any race or sex. Until recently many held that it was related to *Filaria bancrofti* or *Loa loa* infestation, but that view has now been abandoned. Sayers has shown in the Solomon Islands that patients do not generally give positive intradermal tests for filariasis. Various organisms, including *Staphylococcus aureus*, *Streptococci* and a small bacillus, *B. serofaciens* isolated by Scott in Jamaica, may have a causal relationship. At times the disease may almost assume epidemic proportions as in the outbreak on the island of St. Kitts.

Pathology. The pathological findings are those of an acute coccal inflammation of muscle with serous effusion or actual pus formation. In fatal cases pyæmic abscesses or stigmata of septicæmia are found.

Symptoms. Both the local and systemic manifestations vary within wide limits. Fever, pain and stiffness in the affected muscles, and the appearance of multiple, indurated nodular swellings which may or may not break down and suppurate, are commonly encountered. A neutrophil leucocytosis of 15,000–25,000 cells per c.mm. is the rule. Local complications include synovitis, arthritis and periostitis; while in severe cases pyæmic manifestations including pulmonary abscess or even septicæmia may ensue with fatal consequences. The disease may run a protracted course with numerous relapses.

Diagnosis. The condition has to be differentiated from glanders, melioidosis, filarial abscess and intramuscular gummata (Manson-Bahr).

Treatment. Rest, fresh air, and a nutritious high vitamin diet are important. Abscesses may be incised and drained. In relapsing cases autogenous vaccines are worth a trial or non-specific protein therapy (T.A.B. vaccine) in intractable cases. Intercurrent diseases like syphilis and ankylostomiasis should receive appropriate treatment.

Diseases due to Fungi (Mycoses)

Certain fungoid infections are essentially tropical in distribution, namely, mycetoma, dhobie's itch and Hong-Kong foot due to *Epidermophyton inguinale*, Tokelau ringworm due to *Tinea imbricata*, the peculiar pigmented condition of the skin known as pinta, fungoid infections of the hair (trichosporosis or piedra and trichomycosis) and ringworm of the nails (onychomycosis).

Sporotrichosis, blastomycosis, actinomycosis, and torulosis and aspergillosis are in no way peculiar to warm climates and are described elsewhere.

Moniliasis. Yeast-like fungi are undoubtedly capable of producing infections of the skin, intertrigenous dermatitis, involvement of the nails with paronychia and onychia, mouth thrush and membranous lesions in the vagina, but it is exceedingly doubtful if they ever produce primary moniliasis of the digestive tract. Certainly sprue has no primary ætiological relationship to *Monilia ashfordi*. Monilia infection of the broncho-pulmonary system has been described on a number of occasions.

Rhinosporidiosis. This is a chronic disease caused by *Rhinosporidium seeberi* which produces nasal polypi and papillomata of the cheek, conjunctiva, lachrymal sac, penis and vulva.

Ætiology. The disease has been recorded from India, Ceylon, Cochin China, the Argentine and North America, and it has recently been shown by Ashworth to be due to a yeast-like fungus, *Rhinosporidium seeberi*, belonging to the Phycomycetes. O'Kinealy in 1903 found it in nasal polypi in India. The polypi show round-cell infiltration, epithelial proliferation and fibroblasts in which the large cysts containing daughter cysts in a cellulose coating are found.

Symptoms. As the nose is commonly involved, nasal symptoms predominate and a history of nasal discharge with intermittent hæmorrhages may be obtained, extending over several years. The nasal polypi are soft and vascular, bleed easily and tend to recur.

Treatment. In Madras, Wright has noted disappearance of nasal polypi after a course of tartar emetic intravenously. Generally the polyps have to be removed surgically by a wire snare.

MADURAMYCOSIS

(*Madura foot* ; *pseudo-actinomycosis* ; *fungus foot* ; *mycetoma*)

Maduramycosis or mycetoma is a chronic granulomatous disease usually limited to the lower extremities which is caused by various species of fungi.

Ætiology. The disease is particularly common in India (Madura) and also occurs in Egypt, the Sudan, Algiers, Madagascar, Ceylon, Cochin China, the West Indies, South America and the United States. It is generally confined to country districts and there is frequently a history of traumatic abrasions, cuts or thorn pricks in natives who go barefooted. People of any age or sex are susceptible.

A number of different species and genera have the ability to produce granules in human tissues, the two main groups being the Actinomycotic and the Mycetomatous varieties. These granules present in the discharge from the sinuses are composed of hyphæ with or without chlamydospores and other types of spores and vary in size from 1 to 7 mm. in diameter. They may be hard, soft or cheesy in consistency ; their colour may be white, grey, yellow, brown, black or red.

Pathology. The tissues are softened and jelly-like in consistency, containing sinuses with cystic dilatations which communicate with the external nodules and internal granulomatous infiltrations and involve the muscles and bones, forming a honeycombed cheesy mass. For diagnostic purposes the granules are mounted in a 10 per cent. potassium hydroxide on a glass slide, and flattened out with a cover slip. They are best cultured on Sabouraud's maltose medium, being most evident after four to seven days' growth at 37° C.

Symptoms. The onset is generally insidious in character. In the majority of patients a history of trauma of the naked foot is forthcoming; pain, tenderness, swelling and discoloration of the skin may follow, or there may be a latent and symptomless period until the hard, painless nodules develop. According to Carter the initial lesion may consist of a mottled papule, a deep-seated, fixed nodule, a swollen vesicle or an abscess communicating with a fistula. Though the feet are generally involved, the nose, face and abdominal wall have also been occasionally implicated. Unlike actinomycosis, systemic involvement does not occur. Adenitis, if it be present, is due to secondary bacterial infection. After several months the lesions increase in size and number, the nodules ulcerate and sinuses form, from which is discharged a foul-smelling, semi-purulent fluid containing the characteristic granules. Even in advanced cases pain and hæmorrhage are generally absent, but the foot becomes gradually enlarged, and its concavities obliterated. Secondary infection may occur with serious consequences.

Diagnosis. The presence of swelling, nodules, fistulæ and sinuses from which pus-containing granules are exuded, should arouse suspicion. Curettage and irrigation of the fistulæ should be tried if granules are not demonstrable in the ordinary exudate. The differential diagnosis includes yaws, syphilis, tuberculosis, coccidioidal granuloma and sporotrichosis.

Prognosis. The course of the disease is essentially chronic, extending over many years. There is no tendency to spontaneous cure, and death ultimately results from cachexia or secondary infection, unless proper treatment be instituted.

Prevention. Proper foot-wear should be worn and walking barefoot should be avoided. Where abrasions and wounds occur, they should be treated with iodine and protected by appropriate dressings.

Treatment. Excision and curettage of the nodules, followed by X-ray irradiation are indicated in the earlier cases; where the tissues are riddled with sinuses amputation alone holds out a reasonable prospect of cure. This operation, if properly planned, is almost invariably successful. Drugs, including potassium iodide, bismuth sodium tartrate and neosalvarsan are of doubtful value.

Coccidioides. (*California disease*; *Coccidioidal granuloma*.) An infectious granulomatous disease due to *Coccidioides immitis*; it may manifest itself in localised skin lesions, or as a systemic infection which proves rapidly fatal.

Ætiology. The disease occurs endemically in North America (43), Canada, Brazil and the Argentine. It specially affects males and is most prevalent amongst labouring and agricultural classes. *Coccidioides immitis*, as seen in pus, appears as a spherical fungus with granular protoplasm and a double contoured capsule; it measures 5 to 6 μ in diameter and reproduces by endosporulation. It is readily cultured on serum agar at body temperature and appears as a mycelial network with long septate hyphæ; chlamydospores and conidia form in old cultures.

Pathology. The lesions are granulomatous in nature, commencing as tiny nodules, which later may undergo necrosis, caseation, abscess formation, cavitation, fibrosis and even calcification. The histological picture may bear a close resemblance to tubercle.

Symptoms. The disease takes the form of local dermic lesions with or without systemic involvement. The cutaneous and subcutaneous lesions

consist of nodular ulcers involving the dermis or deeper abscesses, gummata or flaccid tumours. The superficial lymph glands of the neck and supra-clavicular region may enlarge, adhere to the skin, break down and ulcerate. Involvement of the lungs is not infrequent. The onset in the acute primary types is accompanied by chilliness, fever, headache and pains in the bones, joints and chest; cough also develops, but true hæmoptysis is rare in early cases. The physical signs are those of pulmonary disease, and tuberculosis is generally diagnosed. The course as a rule is fatal in six weeks to nine months, but in the type secondary to bony or skin lesions the disease is more chronic. *Coccidioides cerebro-spinal meningitis* may occur as a terminal event in systemic infection, and more rarely primary involvement has been recorded. The cerebro-spinal fluid is under increased pressure and contains globulin, many polymorphonuclear leucocytes and *C. immitis*. Coccidioidal involvement of bones and joints is common in generalised infection, and as a rule is accompanied by skin lesions. Fluctuation in the joint may be elicited and on incision, creamy or sanguineous pus containing *C. immitis* is found. A permanent fistula may result. In addition, metastatic visceral involvement may occur in systemic coccidioides. The blood shows a moderate or marked neutrophil leucocytosis and often a secondary anæmia.

Diagnosis. The disease is protean in its manifestations and apt to be confused with tuberculosis, syphilis, yaws, blastomycosis, sporothricosis, mycetoma and epithelioma. Diagnosis is made by demonstrating *C. immitis* in tissue sections, in smears of pus or in the cerebro-spinal fluid. Inoculated guinea-pigs die with systemic coccidioides.

Prognosis. The disease is essentially progressive, its duration varying from a few weeks to several years. If modern treatment be instituted early, the progress is good in the subacute and chronic cases, but acute cases invariably die in from four to twenty-four weeks.

Treatment. The best treatment appears to be intramuscular injections of colloidal copper every four to seven days combined with injections of coccidioidin (a mixture of the endo and exotoxin of *C. immitis*) cutaneously every eight to fourteen days, according to the local and constitutional reaction of the patient (Jacobson). Carbon dioxide snow applied without pressure may prove useful for the local lesions, and general measures include a nutritive diet, rest, fresh air, cod-liver oil *per os* and glucose combined, if necessary, with insulin injections, 1 unit to each 3 grammes of sugar. Surgery, X-rays, iodides and tartar-emetic have all been employed with doubtful benefit.

Spirochætal Diseases

The spirochætes form an important group of micro-organisms, the vegetable or animal nature of which has not yet been determined. They are elongated, flexible organisms, showing spiral movement and sometimes, in addition, undulations of the whole body and often require special staining or dark ground illumination for their demonstration. The tissue-inhabiting forms such as *Treponema pallidum* require anaerobic conditions for growth, while the blood spirochætes such as *Treponema recurrentis* are aerobic. Noguchi recognised three genera—*Spirochæta*, *Treponema* and *Leptospira*. Spirochætes are the causative agents of syphilis, yaws, relapsing fever and leptospirosis, while they are constantly present in Vincent's angina, bronchial spirochætosis and tropical ulcer. The *Spirilla*, being non-flexible organisms, are not true spirochætes so that, strictly speaking, rat-bite fever which is caused by *Spirillum minus* should not be included in the present chapter.

YAWS

(*Frambæsia*, *Frambæsia Tropica*, Pian)

Ætiology. Yaws is chiefly a tropical disease and is found in tropical and subtropical Africa, Ceylon, Burma, Southern Assam, Malaya, Indo-China,

Southern China, the Philippines, Oceania, the northern part of South America including Brazil and the West Indies. A few isolated foci occur in India. It affects almost exclusively dark-skinned races as a disease of childhood: both sexes are susceptible. The causative spirochæte, *Treponema pertenue* (44), which invades the tissues through abrasions on the skin, is indistinguishable from *T. pallidum*, the cause of syphilis, except by its distribution in the tissues. Some authorities would identify the two diseases, regarding yaws as syphilis of premature races, but yaws is of non-venereal origin, is never congenital and does not produce abortion or involve the viscera and central nervous system.

Pathology. The primary lesion and the secondary papules are caused by spirochætes lodged in the epidermal layer; histologically there is downgrowth of dermal epithelium into the corium with leucocytes, plasma cells and fibroblasts. Spirochætes are not present in the corium as in syphilis, nor are the blood vessels involved.

Symptoms. The incubation period varies from two to four weeks and may be accompanied by mild fever, generalised toxic pains and gastro-intestinal features. The primary lesion is extra-genital and usually single; the corresponding lymph glands may be hard and tender. In the secondary stages there is intermittent fever, headache, pains in the bones often worse at night, and arthralgia. The rash develops eight to sixteen weeks after infection while the primary lesion may still be present. First the skin becomes scaly, then small papules resembling the primary lesion appear and increase in diameter up to 1 cm., sometimes coalescing to form larger masses. Desquamation of the cuticle over the papule results in a raw, raspberry-like surface which exudes yellowish serum: this dries and forms crusts resembling syphilitic rupia. Finally, the papules dry up and heal leaving evidence of their presence in hypo- or hyper-pigmented areas. The papules have a symmetrical distribution, affect the face, neck, arms, buttocks and genitals and may give rise to troublesome itching. Successive crops may appear over a period of from three months to three years. The lesions observed in long-standing cases of tertiary yaws include periostitis, osteitis, tenosynovitis, arthritis, ulceration of the palate and bony caries. Bony lesions may involve the long bones, face, hands and feet; exostoses and periosteal nodes resembling gummata may form while rarefying osteitis sometimes leads to spontaneous fracture. Sabre tibia and "boomerang" leg amongst the Australian aborigines frequently result. Chronic ulcers result from the breaking down of subcutaneous granulomata, often on the site of previous lesions, while yaws nodules involving the soles of the feet produce a painful crippling condition known as clavus or crab yaws.

Gangosa, goundou and juxta-articular nodes are generally regarded as sequelæ of yaws and may appropriately receive consideration here.

Goundou. This condition is found on the West Coast and in Central Africa, Sarawak and South America. It affects both children and adult natives and originates as a hypertrophic osteitis of the nasal processes of the superior maxilla. The symptoms at onset include persistent headache, bony pains worse at night, and a purulent nasal discharge often tinged with blood. Later these features subside, and oval, bilateral, nasal swellings develop which may attain the size of a hen's egg; nasal obstruction and interference with vision may follow. The skull, superior and inferior maxilla, clavicle and other bones may be similarly involved. The condition may need differentiation from syphilitic osteitis, leontiasis ossea and acromegaly. Salvarsan injections, and, in the later stages, surgical removal of the exostosed bone are indicated.

Gangosa. This is an ulcerating rhino-pharyngitis resulting in destruction of the palate, nasal septum and nose, the upper lip being left intact. It occurs in the West Indies, Fiji, British Guiana and Central, West and East Africa and Australia; both native children and adults are affected. Severe pain, nasal discharge and foetid breath result, and in severe cases the voice may be affected.

Finally, the eyes and lacrymal ducts may be implicated and much of the face destroyed. Syphilis, leprosy and American dermal leishmaniasis may sometimes be confused with gangosa, which runs a very chronic course, resulting in death from sepsis or insufflation pneumonia. Salvarsan injections should be given in the early stages and plastic operations undertaken at a later date, though conditions in the tropics rarely permit this being done.

Juxta-Articular Nodes. These are multiple, oval periarticular nodules affecting native children and adults in Equatorial Africa, the West Coast, Java and Siam. Microscopical sections reveal avascular, fibrotic tissue containing areas showing polymorphonuclear infiltration and necrosis. The tumours occur in the vicinity of joints, especially the knee and elbow, and on palpation they feel hard and are painless. They may disappear spontaneously, remain constant in size or gradually attain the dimension of a hen's egg. At first the skin is freely movable over the surface; later it becomes adherent but never breaks down, ulcerates or suppurates. Similar lesions may occur in syphilis and the differential diagnosis lies between rheumatic and syphilitic nodules and onchocerca tumours. The latter are, however, soft and semifluctuant, and on needling fluid containing filarial embryos is aspirated; biopsy will also confirm the diagnosis.

Diagnosis. The Wassermann reaction does not help to differentiate yaws from syphilis as it is positive in both diseases, but *T. pertenue* can readily be isolated from yaws nodules. The absence of a primary genital chancre is not conclusive, as chancres are often not found in female syphilitics and are always absent in congenital lues. In differentiating tertiary yaws from syphilis the absence of visceral, vascular and nervous involvement and the rapid therapeutic response to salvarsan may be of assistance. Leprosy, tubercle, dermal blastomycosis and cutaneous leishmaniasis may produce lesions which require differentiation from those of yaws.

Prognosis. Yaws is rarely fatal, runs a prolonged course if untreated, but readily responds to modern specific therapy.

Prevention. Isolation is impracticable, and the most feasible methods of prophylaxis consist of protecting wounds and abrasions and giving specific treatment on a large scale.

Treatment. Certain organic arsenicals and bismuth salts act as specifics; potassium iodide may be useful, but mercury is of no value. Novarsenobillon administered intravenously in doses of 0.6 to 0.9 grammes in adults and in correspondingly decreased amounts to children gives most excellent results: this drug may also be given intramuscularly. While one injection may clear the case clinically, a course of six or more injections is advisable to prevent relapse. Bismuth salts are very effective and are much cheaper for large scale therapy in native races. Sodium-potassium-bismuth tartrate in freshly prepared and boiled solution may be given intramuscularly to an adult each week in a dosage of 0.1 to 0.3 grammes; children tolerate the drug even better than adults, but stomatitis is an unpleasant complication. Other preparations of bismuth, including sodium-bismuth-tartrate, bismuth salicylate, dermatol and halasol, have been used with satisfactory results, though to date less information is available regarding their permanency of cure.

Relapsing Fever. There are two main types—one transmitted by body and head lice and the other by argasine ticks. The varieties transmitted by lice include European relapsing fever due to *Tréponema recurrentis*, discovered in Berlin by Obermeier in 1868, North African relapsing fever produced by *T. berberum*, Indian or Asiatic relapsing fever caused by *T. carteri*, and North American relapsing fever attributed to *T. novyi*. The varieties transmitted by the argasine ticks include Central African tick fever due to *T. duttoni* transmitted by *Ornithodoros moubata*, Somaliland tick fever transmitted by *O. savignyi*, Persian and North-West Indian relapsing fever caused by *T. persicum* and transmitted by

O. tholozani or *O. lahorensis*, Spanish relapsing fever attributed to *T. hispanicum* and transmitted by *O. moroccanus*, Central American relapsing fever due to *T. venezuelense* transmitted by *O. venezuelensis*, and Panama relapsing fever due to *T. neotropicalis* transmitted by *O. talaje*.

LOUSE RELAPSING FEVER

(*Spirochaetosis*, *Febris Recurrens*, *Spirillum Fever*, *Famine Fever*)

A febrile disease characterised by two or more bouts of fever caused by the spirochæte, *Treponema recurrentis*, and transmitted by lice.

Etiology. This disease is endemic in certain places, but like typhus it tends to occur in epidemic form over large areas and is particularly common during famine and war. Male adults are most frequently attacked, though women and children may be affected. Mackie (45) suggested the body louse as a vector, the details of transmission being subsequently worked out by Nugent, Foley and Nicolle. When a louse has fed on infected blood the ingested spirochætes rapidly disappear, but after a few days reappear in the cælotomic fluid; thereafter the louse remains infective for life. Crushing of such lice liberates spirochætes which gain entrance through scratches on the skin or louse punctures.

Pathology. Jaundice is not infrequent and petechial hæmorrhages may be found in the skin. The spleen is enlarged, soft and congested and a frequent site of infarction. The liver is also enlarged and hyperæmic, while the kidneys and heart show cloudy swelling and fatty degeneration. Microscopically spirochætes are demonstrable in the endothelial cells of the liver, spleen and other organs.

Symptoms. The incubation period is five to seven days, the limits being two to twelve. The onset is sudden with rigor, frontal headache, severe pains in the limbs and back and a temperature rapidly rising to 103°–105° F. Anorexia, nausea, vomiting, constipation and photophobia are common. Convulsions may occur in children, while epistaxis is a feature of some epidemics. The face is flushed, the conjunctivæ injected, the pupils contracted, and the tongue dry-coated and occasionally ulcerated. The spleen is enlarged and tender and so generally is the liver. Bronchitis and cardiac dilatation not infrequently develop. A macular rash or even petechiæ occur in some 10 per cent. of cases, specially around the neck and shoulders.

The spirochetes, which stain readily with Romanowsky stains, are scanty in the blood smears at the onset of fever, but steadily increase until twenty-four hours before the crisis when they rapidly disappear again. If blood collected between attacks be injected into white mice or guinea pigs spirochetes appear in twenty-four hours. A neutrophil leucocytosis accompanies the pyrexia and a leucopænia the afebrile period. The "adhesion" test may be positive: it depends on the fact that in immune but not in normal serum spirochetes and platelets clump together. The urine is decreased in quantity and sometimes contains spirochætes: albumin is present, and in severe cases granular and hyaline casts may be found. As a rule the primary fever lasts about a week, but may be as short as three or as prolonged as twelve days: its termination is by crisis with sweating, subnormal temperature, and occasionally collapse with cardiovascular failure. Relapses by no means invariably occur, but the second bout of fever generally appears about the thirteenth or fourteenth day, and as a rule is not as prolonged as the primary fever (see Fig. 98, p. 1034). A third relapse is not common and a fourth relapse rare.

Complications include parotitis, jaundice, bronchitis, broncho-pneumonia, nephritis, cardiac failure and rupture of the spleen. Hæmatemesis and hæmaturia occur in epidemics where there is a high incidence of jaundice.

Diagnosis. The mode of onset, type of temperature chart and splenomegaly will suggest the diagnosis which is readily confirmed by demonstrating the spirochetes in blood smears. Influenza, dengue, malaria, typhus and para-

typhoid need differentiation in cases which do not relapse, and yellow fever and Weil's disease where jaundice has supervened.

Prognosis. The mortality rate varies considerably in different epidemics and averages 10 to 15 per cent. It is particularly fatal in the aged and debilitated, its worst ravages being seen in times of famine.

FIG. 98.—Temperature in Relapsing Fever.

Prevention. This follows the lines already suggested in typhus and consists of delousing and isolating cases, etc.

Treatment. Absolute rest in bed, careful nursing, light diet and abundance of fluids are essential. Injections of novarsenobenzol (0.6 grammes) and neo-salvarsan (0.4 grammes) given intravenously in 10 c.c. of distilled water are curative:

TICK RELAPSING FEVER

A disease characterised by repeated bouts of fever caused by *Treponema duttoni*, the spirochætes being transmitted by certain argasine ticks notably *Ornithodoros moubata*.

Ætiology. Christy first described the disease in East Africa. Ross and Milne (46) subsequently demonstrated the spirochætes in the blood and Dutton and Todd proved transmission by *Ornithodoros moubata* the following year. In Equatorial Africa the disease is localised to certain houses and camping places infested with ticks, which, once infected, remain so for life and transmit the infection to their offspring. The infected arthropods which live on the ground and in crevices in walls and floors, generally come out and bite at night while the person is sleeping. Spirochetes are present in the salivary glands, the coxal fluid and the anal excrement and from these sources man acquires the disease.

Pathology. The morbid anatomy is similar to louse relapsing fever, but congestive changes in the cord and brain and iritis are more characteristic of *T. duttoni*.

Symptoms. The clinical picture resembles that of louse relapsing fever except that the bouts of fever are more intense and of shorter duration. The average number of relapses is five or six, but there may be as many as twelve. The afebrile intervals also tend to be longer. Diarrhoea, iritis, spastic paralysis, facial neuritis and other nerve palsies are more frequently observed than in louse-borne relapsing fever.

Diagnosis. This presents little difficulty though the spirochætes are fewer and in consequence more difficult to demonstrate in blood smears: laboratory animals are readily infected by blood inoculation.

Prognosis. The mortality rate approximates to 5 per cent.

Prevention. Disinfection of camping grounds and infected houses should be practised and infected sites avoided. Ticks are removed by the local application of kerosene or turpentine and a drop of pure carbolic is subsequently applied to the bite.

Treatment. This is identical with that outlined for louse relapsing fever.

Leptospirosis is the name for several kinds of fever caused by leptospiræ which lodge in the kidneys of rodents and are passed in the urine; thus they contaminate water and fungal slime which are the usual sources of human infection. The best known of these organisms is *Leptospira icterohæmorrhagiæ* which causes classical Weil's disease, but in many countries more than one serological type has been isolated differing from the classical "Weil" strain on agglutination (47). Thus three or four strains have been isolated in both Japan and Sumatra, five in Malaya and two amongst outbreaks of Weil's disease in Indian convicts on the Andaman Islands where the predominant strain appears to be identical with "Rachmat" and "Deli" A of the Dutch East Indies.

L. hebdomadis, which occurs in field mice, gives rise to a seven-day fever in Japan and a spirochæte serologically identical has been reported from Sumatra, Panama and the Sudan. In Europe there are three varieties—*Leptospira icterohæmorrhagiæ* (classical "Weil" strain) which gives rise to spirochætal jaundice in man and dogs, *L. grippotyphosa*, the cause of swamp fever, characterised by seven to fourteen days' fever with a variable rash but without jaundice, and *L. canicola* which is a specific disease of canines capable of infecting man.

WEIL'S DISEASE

(*Spirochætal Jaundice*, *Spirochætosis Icterohæmorrhagica*, *Leptospirosis*, *Infective Jaundice*)

A febrile disease of sudden onset which may be associated with jaundice occurring about the fourth to the sixth day.

The causative organism, *L. icterohæmorrhagiæ*, which was discovered in 1915 by Inado and Ido in Japan (Fig. 99), is located in the kidney of rats in practically

FIG. 99.

- A. *L. icterohæmorrhagiæ*, from blood of inoculated guinea-pig
 B, C. *L. icterohæmorrhagiæ*, from human blood on second day of the disease before jaundice had appeared.
 D. *Treponema pallidum* (upper figure) and *Treponema refringens* (lower figure), from primary syphilitic sore. Magnitude 2,500. (After A. C. Coles.)

all countries where surveys have been made; from this source infection arises. The leptospiræ gain access to rat-infested canals and rivers and either transverse the mucous membranes during bathing or "immersion" accidents or gain access *viâ* the abraded skin. Canal workers and bargemen are not infrequently infected. The disease is common in countries like Egypt and Holland where canals abound, and in Japan in river and swampy country, but not where it is high and dry. In addition, the leptospiræ thrive in the fungal slime found on the

walls of coal mines, sewers, gutters and floors of abattoirs and fish shops where rats congregate to feed on offal. This is why Weil's disease is so frequently an occupational one as in coal miners (48), sewer builders (49), gutter sweepers, fish workers, cane cutters and the like, the leptospiræ gaining access through the abraded skin. Wet, rat-infested trenches were a potent source of infection during the Great War.

Pathology. Jaundice of variable degree is present and petechial hæmorrhages may be observed in the skin, mucous and serous membranes and viscera. The liver is enlarged and bile-stained and on histological section shows fatty degeneration or necrosis of the hepatic cells, while in extreme instances a condition allied to acute yellow atrophy may develop. The kidneys are swollen and jaundiced; there is wide-spread degeneration of the convoluted tubular epithelium, the lumina of which may contain bile and blood casts. The spleen is congested though not necessarily enlarged, the myocardium pale and fatty and the endocardium bile-stained.

Symptoms. The incubation period varies from six to twelve days. The

FIG. 100.—Temperature charts in two London sewer workers dying from Weil's disease.

onset is sudden with rigors, headache, vomiting, sore throat, pains in the joints and intense pain and tenderness in the muscles. The patient is completely prostrated, the blood pressure low, the tongue furred, the face flushed and the conjunctivæ and throat injected. The temperature continues to rise, usually oscillating between 102° and 104° F., until the fourth or fifth day when it begins to fall by lysis or more rarely by crisis; the normal is generally reached in seven to fourteen days. Jaundice, which may be very intense, appears about the fifth day, but it may be as early as the second or as late as the seventh in onset. The stools are light brown or occasionally clay-coloured where the obstruction is complete. There is hyperbilirubinæmia and the van den Bergh gives a biphasic or delayed direct reaction. The urine is scanty and contains albumin, bile pigments and sometimes red blood corpuscles. Leucocytosis is marked, amounting to 12,000 to 30,000 per c.mm.; the neutrophil polymorphonuclears are markedly increased and average about 80 per cent. of the total white cells. Skin petechiæ may appear from the third to the fifth day and in addition there may be hæmorrhages from the mucous membranes, the most frequent being epistaxis and malæna. Herpes is common in some epidemics, its incidence being 40 per cent. amongst British troops on the Western Front.

Prior to the onset of conjunctival congestion and jaundice, physical examination may reveal extreme tenderness especially in the calf, neck and abdominal muscles, the patient sometimes calling out with pain when he is being moved in bed. In some instances abdominal rigidity is so marked that an acute abdomen is suspected and the patient may be erroneously operated on, especially if hæmatemesis co-exists. Splenomegaly may or may not be present, but tenderness and enlargement of the liver are the rule. Sleeplessness, nocturnal delirium, a typhoid state or muscular twitchings and convulsions may develop in severe cases and patients may die with anuria associated with marked nitrogenous retention, the blood urea reaching 400 to 500 mg. per 100 c.cm. In other cases cholæmia may develop, associated with drowsiness, hiccup, Cheyne Stokes' respirations, coma and death. In about 50 per cent. of cases jaundice is absent, while renal involvement is minimal. Under these circumstances there is a short febrile attack perhaps terminating by crisis in two to four days, associated with muscle pain, tenderness and transient albuminuria. In cases which recover there is generally no secondary rise of temperature, but occasionally there is a recurrence of fever in the third week associated with an increase in the agglutinin titre of the blood.

Complications include cardiovascular collapse, cholæmia, anuria, iritis, iridocyclitis and alopecia. Convalescence is gradual, but recovery is complete.

During the first week leptospiræ can be cultivated on Fletcher's or Noguchi's serum medium which is inoculated with about 0.5 c.cm. of the patient's blood and incubated at 28° C. A more reliable test consists of the intraperitoneal injection of 2 to 4 c.c. of blood into a guinea-pig which develops fever, hæmorrhages, albuminuria and finally jaundice. Leptospiræ may be found in smears from the liver and kidney and sometimes in the heart blood: subinoculations should be made. In man, after the eighth day leptospiræ disappear from the blood, but subsequently they may be demonstrable for several weeks in the urine either by dark-ground examination or animal inoculation. Schüffner's agglutination test (47) and the adhesion test of Brown and Davis (50) are also applicable, and are of considerable diagnostic value after the first week.

Diagnosis. The sudden onset of fever characterised by shivering, profound prostration, great muscular pain and tenderness, severe jaundice appearing about the fourth to the sixth day, hæmorrhages, albuminuria and leucocytosis should leave little doubt, especially if the occupation or history suggest contact with rat-infested water or slime. Catarrhal jaundice may present difficulties, but the premonitory gastro-intestinal symptoms, the absence of hæmorrhages and renal involvement and the presence of lymphocytosis associated with a normal white count or leucopænia favour the diagnosis of catarrhal jaundice. Yellow fever also may closely simulate Weil's disease and the demonstration of leptospiræ in blood or urine or specific agglutination tests may alone establish the diagnosis. Relapsing fever complicated by jaundice may also prove confusing.

The atypical and mild types of leptospirosis have to be differentiated from tonsillitis, influenza, dengue and the sand-fly group of fevers, and laboratory data are essential for this purpose.

Prognosis. The mortality varies from 10 to 50 per cent. Cardiovascular collapse, severe hæmorrhages, anuria and cholæmia are ominous features.

Prevention. This consists of rat destruction, avoidance of bathing in infected canals and the protection of skin abrasions in workers whose occupations make them liable to contact with infested slime. Prophylactic vaccine therapy in sewer builders and the like might help.

Treatment. General treatment along the lines laid down for yellow fever should be instituted. Intravenous glucose solution (5 per cent.) is of special value. In addition anti-leptospiral serum prepared from immunised horses should be administered intravenously as early as possible, 60 c.c. being given in twenty-four hours. If this be not available convalescent human serum in a dosage of 30 c.cm. daily may be substituted.

Japanese Seven-day Fever (*Nanukayami*). A febrile disease lasting about a week and resembling mild Weil's disease clinically. The cause is *L. hebdomadis* which infects the kidneys of field mice, the natural reservoir of infection. *L. hebdomadis* differs serologically from *L. icterohæmorrhagiæ*. It is found in the blood during the first week and may be demonstrated by blood culture or guinea-pig inoculation. The leptospiræ subsequently lodge in the kidneys and appear in the urine from about the eighth to the fortieth day. The natural reservoir is the field mouse, *Microtus montebelloi*: in endemic areas of infection about 3 per cent. show leptospiræ in the urine. Agricultural labourers and foresters probably acquire the disease handling infected soil.

Symptoms. The onset is sudden, accompanied by fever which lasts seven days. Prostration and muscular pains are marked, gastro-intestinal disturbances are troublesome, there is furred tongue, injection of the conjunctivæ, enlargement of the lymphatic glands, albuminuria and leucocytosis. Jaundice is infrequent.

Treatment. Specific serum therapy is unnecessary since recovery is invariable.

RAT-BITE FEVER

(*Sodoku. Rat-Bite Disease*)

A chronic relapsing type of fever transmitted by the bites of rats and other rodents harbouring *Spirillum minus*; there is inflammation and ulceration of the healed bite, lymphangitis, adenitis, fever, rigors and a macular or papular purplish rash.

Ætiology. The disease is most common in Japan, China and Bombay, but it also has been reported in England and other European countries, East Africa, West Indies and Australia. The infective agent, *Spirillum minus* (51), is a short organism with two to six curves which are very difficult to find in human or animal blood smears owing to their scantiness and small size. About 3 per cent. of house rats in Japan are carriers.

Pathology. Inoculated animals show congestion and swelling of the lymph glands and spleen where spirochætes are found in considerable numbers, and human cases show degenerative changes in the liver and kidneys.

Symptoms. Some two to six weeks after the wound has healed intense pain and swelling occur at the site of the bite which becomes inflamed, breaks down and ulcerates. Lymphangitis and adenitis follow and a series of small vesicles may surround the local lesion. Rigor and temperature now develop, associated with headache, shivering and prostration; nausea, vomiting, joint pains and diarrhœa may follow and in some cases an erythema or a macular purplish rash appears over the limbs, trunk and face: occasionally skin petechiæ or urticaria are seen. After three to eight days the temperature subsides, often by crisis, and the symptoms ameliorate or disappear. The improvement, however, is only temporary, for in a few days fever and other symptoms return. Repeated relapses occur, about six days intervening between the onset of fever in successive bouts. This state of affairs may continue for many months and result in marked debility. Complications include nephritis, paresis and exophthalmos. A leucocytosis with eosinophilia accompanies the fever.

Diagnosis. The history of rat-bite and the breaking down of the local lesion associated with lymphangitis, adenitis and fever recurring every five or six days should arouse suspicion. Spirilla are difficult to demonstrate in smears of blood and white rats or mice should preferably be inoculated for this purpose.

Prognosis. About 10 per cent. of Japanese patients succumb to the disease, but with modern treatment death should not occur.

Treatment. Immediate cauterisation of the bite may prevent infection. Salvarsan or one of the allied arsenical preparations are curative and the injections should be given during the fever at any time except just before or during the crisis.

Protozoal Diseases

Protozoa are unicellular organisms, containing cytoplasm, a nucleus, nuclear membrane, and chromatin, which ingest preformed proteid material in solution or as solid particles (Wenyon) (52). They may live a free aquatic life, or be intimately associated with animals as commensals, symbionts, or parasites. Though of little importance in temperate climates, the pathogenic protozoa constitute the most important group of organisms infecting man in the tropics and subtropics.

MALARIA (Plate 67, 5-16, p. 1053)

(Paludism. Ague. Marsh or Jungle Fever)

Malaria, the greatest menace of the tropics, is an endemic and epidemic disease caused by at least four species of *Plasmodium* which affect the red blood corpuscles and give rise to periodic fever, anæmia and enlargement of the spleen. Transmission is by infected female anopheline mosquitoes.

Historical. Europe suffered severely from ague in the Middle Ages, and cinchona bark, which was brought back from Peru by the Jesuit Fathers in the first half of the seventeenth century, was of incalculable benefit both in controlling this disease and in enabling Sydenham and other physicians to separate malaria from other fevers. Quinine itself was not introduced until 1820. In the first half of the nineteenth century the dark colour of malarial organs and pigment deposits in certain cells were noted. Laveran, when studying the phenomenon of flagellation, first recognised the pigmented malarial parasite in 1880. Manson, after studying the phenomenon of the flagellation of the male gamete in shed blood in 1894, formulated the hypothesis of mosquito transmission, but he thought that the disease was transmitted by swallowing infected mosquitoes in water, and not through their biting man. MacCallum, three years later, recognised that the flagellating body was a fertilising agent. Ross in 1898 demonstrated the transmission and developmental cycle of bird malaria (*Proteosoma*) in grey mosquitoes (culicines), after having noted the immature oöcysts of human malaria in "dapple winged" mosquitoes (anophelines), and predicted the life cycle in human malaria to be similar to that observed in bird malaria. Later in the same year, Grassi, Bignami and Bastianelli described the complete development of malignant tertian malaria in *Anopheles maculipennis*, and actually transmitted malaria to man by the bite of these mosquitoes.

Ætiology. The malaria parasites affecting man belong to the genus *Plasmodium*. At least four species are recognised: (1) *Plasmodium vivax*, which causes benign tertian malaria; (2) *Plasmodium malariae*, the cause of quartan malaria; (3) *Plasmodium falciparum*, causing malignant tertian or sub-tertian malaria; and (4) *Plasmodium ovale*, which was described by Stephens as recently as 1922. Stephens also described another parasite, *Plasmodium tenue*, in 1914, but its status is doubtful.

Malignant tertian malaria is the commonest variety and has the widest geographical distribution; in the tropics it occurs at all seasons of the year, but in the subtropics it tends to become epidemic in the late summer and early autumn, hence the name of æstivo-autumnal fever. Benign tertian malaria is more common in the more temperate zones; it was responsible for the malaria which flourished in England until the middle of the last century. The three common forms occur in the subtropics, but *Plasmodium ovale* has a very limited geographical distribution in Africa, the few cases reported to date mainly originating in Nigeria. People of all ages may develop the disease, but in endemic areas the infection is commonest in children, who gradually acquire a certain degree of immunity as they grow older. No race is exempt. Immunity probably implies latent infection, and in experimental avian and simian malaria acquired immunity depends on hypertrophy of the reticulo-endothelium system, with augmentation of its phagocytic functions. In India and Africa malaria disappears at a level

above 6,000 feet and in Europe above 3,000 feet. Most of the epidemics studied in the past have been subtropical, and associated with excessive rainfall and malignant tertian malaria. The Ceylon epidemic of 1934 differed. It was strictly tropical; drought conditions due to failure of the South-West Monsoon produced famine, and led to the breeding of the mosquito vector, *Anopheles culicifacies*, in small water holes in the dried river beds in areas of Ceylon where the immunity, as indicated by the spleen rate, was relatively low (Gill). Both species of tertian malaria (*P. falciparum* and *P. vivax*) were equally implicated. Whole villages were depopulated, work ceased in many agricultural areas and 80,000 people died in seven months as a result of the epidemic.

Life History of the Malarial Parasite. While malaria can be transmitted by the injection of blood from an infected patient collected in either the latent or

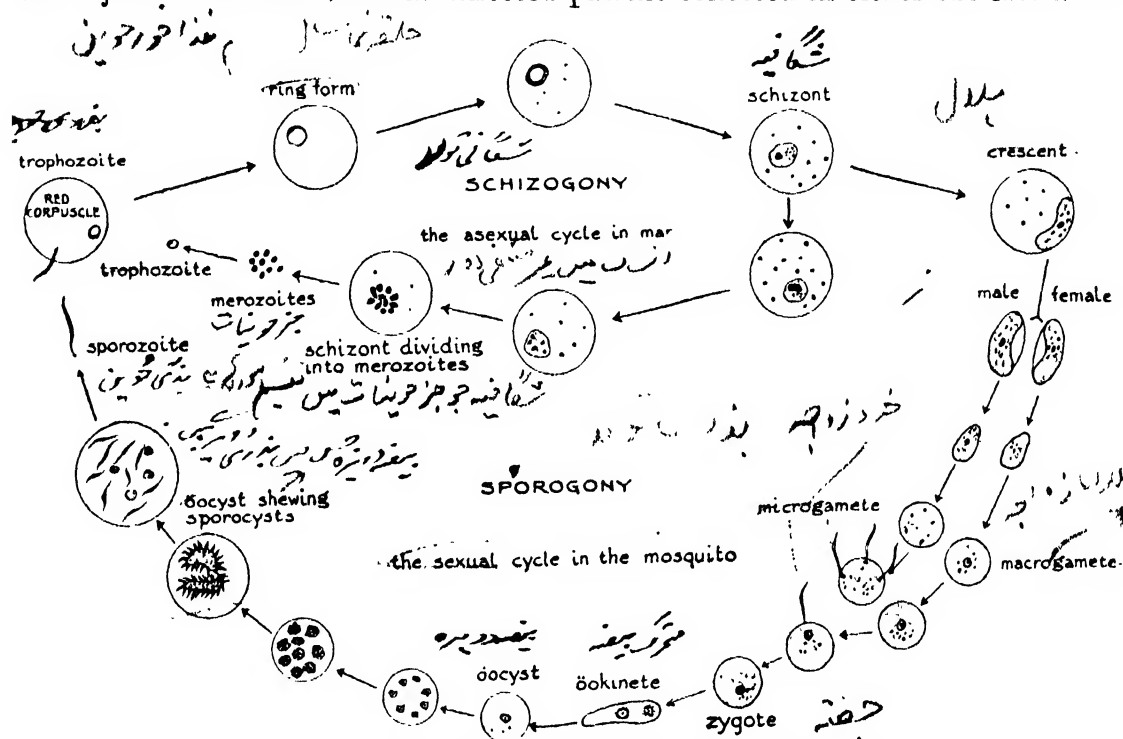

FIG. 101.—Diagrammatic representation of the life cycle of the parasite of malaria.

febrile phase, the disease under natural conditions is only transmitted from man to man through the medium of an infected female anopheline mosquito, which introduces the infecting sporozoites through its hypopharynx at the time of feeding. The parasite undergoes two cycles, one in man and other in the mosquito. In Fig. 101 the life cycle of the malignant tertian parasite is depicted.

Asexual Phase in Man. After the sporozoites are inoculated by the mosquito they pass into the blood stream and enter the red cells where vacuolation of their protoplasm occurs and they change into small rings containing black pigment (hæmozoin). At this stage the parasite exhibits active amœboid movements. The malignant tertian parasite does not affect the size of the corpuscle, whereas the quartan form fills the red cell and the benign tertian parasite actually expands it. As the parasite develops, the pigment collects centrally and the protoplasm and the chromatin divide into spores, forming the sporulating body, rosette or schizont. Later these spores, which are known as merozoites, escape into the plasma, penetrate new corpuscles and restart the cycle. If present in sufficient numbers they give rise to malarial fever, the cold stage of which synchronises with the liberation of the merozoites.

Sexual Phase in the Mosquito. In addition to the forms produced during sporulation in the asexual cycle in man, certain sexual forms or gametocytes appear. These are large, round or oval bodies, filling the corpuscles in benign

tertian infections, and large crescent-like bodies in the case of malignant tertian malaria; when the latter are taken up by suitable mosquitoes they revert to a circular form. From the male gametes flagella separate off (exflagellation) and these penetrate the female gametocytes and fertilise them, the process being known as zygotism. The resulting body, which is known as the travelling vermicle or ookinet, elongates and penetrates into the stomach wall of the mosquito; here it becomes circular in outline and develops into oöcysts, which become finally packed with spindle-shaped sporozoites causing hernia-like protrusions on its surface. These finally rupture and the sporozoites escape into the body cavity and ultimately make their way to the salivary glands. During the act of biting, the infected mosquito inoculates these sporozoites which penetrate the corpuscles and restart the infection. The rate of development in the mosquito is dependent, amongst other things, on the external temperature, and under optimum conditions takes about ten days, while the incubation period in man varies from nine to twenty-one days or longer, according to the species of *Plasmodium* involved.

Parasites in the Peripheral Blood. All forms of benign tertian and quartan parasites, as well as of *Plasmodium ovale*, are met with in the peripheral blood, but in malignant tertian malaria the schizonts are not found, owing to the fact that sporulation occurs in the internal organs. Small hair-like rings and large crescents (gametocytes) are alone present. The parasites are best demonstrated by staining with some Romanowsky stain, such as Leishman's or Giemsa's, and certain features, as emphasised by Wenyon (52), assist in differentiating the different species.

Ring Forms. In malignant tertian malaria the rings only occupy about one-sixth of the cell, which may show Maurer's dots; they are generally fine, hair-like in appearance, often containing two chromatin dots, while multiple infection of the same corpuscle is not infrequent. Irregular and flattened marginal forms occur. The rings of *Plasmodium vivax* and *Plasmodium malarix* are much larger and thicker and contain more cytoplasm, occupying about one-third of the corpuscle; occasionally *Plasmodium vivax* may show multiple infection of the same corpuscle, though this is rare. The species cannot be determined if only one ring be found.

Partially Grown Forms. In *Plasmodium vivax* the Schüffner's dots are often scattered through the corpuscle, which tends to be enlarged and contain parasites which are irregular in shape and show light-brown pigment. With *Plasmodium malarix* Ziemann's stippling may be demonstrated in the red cells, which are not enlarged; the trophozoite resembles a signet ring, the pigment is dark brown or black and the parasite tends to stretch across the corpuscle producing a band-like form.

Adult Forms. The schizonts of *Plasmodium vivax* have sixteen and those of *Plasmodium malarix* eight merozoites, whereas the gametocytes have a single nucleus and a different distribution of chromatin and pigment. The fourth species of malarial parasite, *Plasmodium ovale*, morphologically resembles *Plasmodium malarix*; the infected corpuscles, however, often show distorted shapes and contain Schüffner's dots.

Pathology. Early in the disease the spleen is soft and of a dark red colour, while in chronic infections it is enlarged, hard and of a dark steel-grey hue due to malarial pigment. Often there is peri-splenitis. The liver may be enlarged and plum-coloured, the lungs congested and oedematous and the intestinal mucosa and peritoneum leaden in colour. The brain and its membranes may present a similar discoloration as well as congestion, oedema and punctate hæmorrhages. Sections reveal malarial pigment in the reticulo-endothelial cells of the liver, spleen, bone marrow, etc., while pigmented mononuclears and leucocytes may be observed in the vessels. The liver, spleen and kidney show the Prussian blue reaction due to deposition of a fine brown iron-containing pigment—hæmosiderin

—in the parenchyl cells. The cells of the liver and the tubular epithelium of the kidneys may show cloudy swelling, fatty degeneration or necrosis, while the capillaries of the internal organs, such as the spleen, intestine and liver as well as the brain, may be blocked with emboli of infected adherent erythrocytes. In fatal benign tertian and quartan malaria severe ankylostome infection, intercurrent pneumonia, sepsis or tuberculosis is generally found.

Clinical Pathology. Considerable blood destruction occurs in malaria, the hæmoglobin being converted into an iron-containing pigment, hæmosiderin, and hæmo-bilirubin demonstrable by the indirect van den Bergh reaction. The hyperbilirubinæmia varies from 1·0 to 6·0 units and is responsible for the mild hæmolytic jaundice so often observed clinically. Hæmo-bilirubin is transformed by the polygonal cells of the liver into choli-bilirubin or bile pigment, pleocholia resulting. This, in turn, produces bilious vomitus and dark-coloured stools containing an excess of stercobilin which on re-absorption gives rise to urobilinuria so characteristic a feature of chronic malaria. In severe infections the blood may become watery and a severe hæmolytic anæmia of normocytic type ensues. Demonstrable hæmoglobinæmia and hæmoglobinuria do not occur in uncomplicated malaria as the destroyed corpuscles are broken up within the reticulo-endothelial cells.

Symptoms. The outstanding clinical features of malaria are fever, splenomegaly and anæmia. During the initial attack the pyrexia is often continuous or remittent in type (primary paludism), and only later may it assume its characteristic periodicity.

I. Benign Tertian Malaria. Attacks of ague generally begin in the forenoon or early afternoon and consist of cold, hot and sweating stages. The cold stage corresponds to the escape of merozoites into the circulation, and the whole phenomenon probably represents a protein shock effect.

(1) *Cold Stage.* The patient feels listless and develops headache, backache, and pain in the limbs, followed by feelings of chilliness. Then the rigor begins. He lies curled up with chattering teeth and shivers so violently that the whole bed shakes. The face is pinched and blue, and the patient covers himself with blankets and rugs in a fruitless effort to keep warm. Though the rectal temperature is considerably above normal, the skin surface at this time is actually cold, due to contraction of the superficial vessels. Vomiting is common and nausea usually present. Toward the end of this stage, which lasts half an hour to two hours, the axillary temperature rises rapidly, attaining a height of 103–106° F.

(2) *Hot Stage.* The body now becomes burning hot and dry and the bed-clothes are discarded. The temperature is high, the arterioles relax, the pulse becomes quick, hard and full, the carotids throb, the face is flushed, the head aches, and in severe cases stupor or even delirium may develop. This stage lasts three to four hours.

(3) *Sweating Stage.* The skin now gradually moistens. Sweating becomes profuse for some hours, pain and discomfort disappears, the pulse slows, the tongue becomes moist, and the temperature falls, slowly at first and then more rapidly till a normal level is reached. When the attack is over the patient feels reasonably well, but after an interval determined by the species and number of the parasites another paroxysm occurs. Usually the paroxysm lasts eight to twelve hours, with forty-eight hours interval between the bursts of fever; cycles developing on consecutive days may result in quotidian fever.

The spleen as a rule is palpable even during the first attack of malaria, and it can often be felt as a soft, tender mass below the left costal margin, moving on respiration. In more chronic cases it is definitely hard and less tender, and in advanced cases may assume large dimensions. Herpes also is common, and a secondary anæmia of moderate degree generally develops. The liver may be increased in size, but this is not as common as in malignant tertian fever. Even if untreated benign tertian malaria rarely lasts more than three years.

II. Quartan Malaria. The rigor and clinical picture are very similar to that of benign tertian malaria. The temperature may rise to 105° F. or 106° F., but the paroxysm is generally shorter, lasting only four to five hours. Single infections generally cause fever every fourth day with a pyrexial interval of seventy-two hours. Cycles on consecutive days may cause two days of consecutive fever with twenty-four hours clear interval on the third day, while treble cycles may produce quotidian fever.

III. Plasmodium Ovale. Though in blood films the parasites look more like quartan malaria, the schizogamous cycle takes forty-eight hours and tertian fever results. The general clinical picture resembles that of benign tertian malaria.

IV. Malignant Tertian Malaria. Three types of fever are met with: (1) the usual tertian type with fever on alternate days; (2) quotidian fever due to a double cycle; (3) continuous irregular or remittent fever attributable to several generations of parasites producing small pyrexial bursts at short intervals. Though chilliness is felt, rigors are not usually present and the temperature rises less abruptly; the hot stage tends to be prolonged and the sweating stage less intense. The whole paroxysm lasts from twelve to eighteen hours. Not infrequently the fever never completely intermits and a remittent type of temperature results. General features, such as backache, headache, nausea, anorexia and vomiting are characteristic, and a severe hæmolytic anæmia may rapidly develop. The spleen though soft is enlarged and tender at this stage and hepatomegaly is common.

Special Forms of Pernicious Malaria. Malignant tertian malaria is very protean in its manifestations, the variable clinical picture being dependent on excessive blood destruction, toxic effects on the renal and hepatic parenchyme cells, and the clumping together of parasitised cells causing plugging of the capillaries in the internal viscera and brain of man. ✓(1) *Hæmolytic Anæmia.* The gravest cases may resemble pernicious anæmia clinically, the counts in extreme instances reaching 1,000,000 to 2,000,000 corpuscles per c.mm. The colour index, however, does not exceed unity, megalocytosis is not marked and the average diameter of the corpuscle is normal. Dyspnoea, palpitation, retinal hæmorrhage, hæmic murmurs, hæmolytic jaundice, bilious stools and dark brown urine are present. (2) *Malarial Jaundice.* There are two distinct types—hæmolytic and toxic. Hæmolytic jaundice is characterised by splenomegaly, bilious vomiting, bilious stools associated with hyperbilirubinæmia, pleocholia and urobilinuria; the indirect van den Bergh is positive and bile pigments and bile salts are absent from the urine which contains a considerable increase in urobilin. ✓Toxic malarial hepatitis presents similar clinical features, but the liver is larger and more tender, epigastric distress is present and hæmorrhage from the gastro-intestine or elsewhere may occur. Jaundice comes on early after the onset of fever, the urine contains bile salts and bile pigments and a direct bi-phasic van den Bergh reaction is often found. Here degeneration of the parenchymatous cells of the liver has supervened. Remittent or intermittent fever may accompany either type, but the old term "bilious remittent fever" has led to considerable confusion in the past and is better abandoned. (3) *Cerebral Malaria.* In cerebral malaria the onset is usually rapid, the patient complains of severe headache, dizziness and drowsiness and may rapidly pass into complete unconsciousness or he may develop hemiplegia, paraplegia, aphasia, convulsions or delirium and mania. The temperature may follow the usual course or hyperpyrexia may develop with cyanosis, stertorous breathing and coma, simulating sunstroke. (4) *Abdominal Malaria.* Gastric, choleraic and dysenteric types of malaria may occur, the clinical features being due to involvement of the stomach, small intestine and large bowel respectively. In algid malaria the temperature falls below normal, and collapse supervenes. The skin is cold and covered with sweat; vomiting and diarrhoea are continuous and intractable, and occasionally blood is vomited or passed *per rectum*. The prognosis in these cases is bad.

Where the peritoneum is implicated peritonism with abdominal pain, vomiting and collapse ensues, and acute pancreatitis, cholecystitis or appendicitis may be erroneously diagnosed. The typhoidal form (typho-malaria) is characterised by a continuous fever with little remission, extending over many days; asthenia and low delirium may develop with a clinical picture resembling that of enteric. Unless the condition be recognised and properly treated, the patient dies. (5) *Cardiac Malaria*. Syncope associated with venous congestion and dilatation of the right heart ensue: the outlook is grave. (6) *Renal Malaria*. Inadequate attention has been paid to this condition, especially in early hyper-infections with malignant tertian malaria; the urine contains albumin and casts, there is urea retention, and unless specific treatment be given uræmia may develop. (7) *Malarial Cachexia*. In those who have had repeated attacks of malaria, and in the natives, children and adults in hyper-endemic areas, the bodily health becomes seriously undermined. Lassitude, anæmia, a sallow, earthy appearance of the skin, dizziness, anorexia, digestive disorders, hypochlorhydria or achlorhydria, and aching in the joints and muscles, are common features. In severer forms there may be œdema or hæmorrhages unassociated with fever. "Ague cake" spleen is characteristic, being hard and often enlarged to below the umbilicus. The liver may also be markedly enlarged and, owing to dyspepsia, cirrhosis or gastric carcinoma with secondary deposits may be suspected.

Complications and Sequelæ. Neuralgia, especially of the superorbital nerve, neuritis, ulceration of the cornea, iritis, optic neuritis, retinal hæmorrhages and occasionally orchitis may occur. Herpes labialis is common, especially in benign tertian infections, while rupture of the enlarged spleen from slight trauma is liable to occur. Nephritis with œdema is especially frequent in quartan malaria. Soft pigment stones may form in the gall bladder as the result of pleocholia, but true malarial cirrhosis never occurs. Malarial fever not infrequently produces abortion and there is much more danger in withholding quinine or atebrian than in administering them in pregnancy.

Diagnosis. Attacks of malaria are often distinguished by their periodicity and this is especially the case with tertian and quartan fevers, the onset of which is often in the forenoon or early afternoon. Daily rigors are less to be trusted as they occur in various septic conditions, including pyæmia, cholangitis, abscess of the liver, pyelitis and malignant endocarditis. Other points of clinical importance are the presence of splenomegaly, secondary hæmolytic anæmia and the laboratory findings. Blood smears should be made before specific drugs are administered. Where parasites are scanty in the peripheral blood more than one examination may be necessary. The finding of pigmented leucocytes, a mononucleosis during the apyrexial period of 15 per cent. or over, and the presence of urobilinuria are all very suggestive. The therapeutic response to specific drugs may or may not be significant.

Prognosis. In tropical countries malaria is the largest factor in the death rate, and is specially serious in the under-nourished, in young children and in those suffering from intercurrent disease like ankylostomiasis. Benign tertian malaria is not generally fatal, except in the debilitated and anæmic, the very young and the very old, but it definitely predisposes to intercurrent infections which are the chief causes of death. Malignant tertian malaria, if untreated, often kills, but following specific treatment this species of parasite is permanently eradicated more easily than either benign tertian or quartan malaria.

Prevention. Mosquito boots should be worn in the evening and residents should sleep under mosquito nets or where possible live in mosquito-proof houses. The application of volatile oils, such as oil of citronella round the ankles, wrists and neck may be useful. Tropical residents should obliterate the breeding places about their bungalows and gardens and frequently inspect the surrounding areas for mosquito larvæ. The destruction of anopheline larvæ and of their breeding grounds by oiling, spraying with Paris green, or drainage,

are important measures in malarial control. Prophylactic quinine prolongs the incubation period and tends to keep the disease subclinical. It fails, however, to prevent malarial infection. Plasmoquine, on account of its specific lethal action on gametocytes, has superior claims to quinine as a true prophylactic.

Treatment. During the attack the patient should go to bed and remain there until after the temperature has been normal for at least three days. A brisk purge is given at the onset of the fever and hot drinks encouraged. Hot bottles and plenty of blankets are appreciated in the cold stage and during the hot stage an aspirin-cafein-citrate mixture is helpful. Frequent hot drinks containing bicarbonate of soda may be given during the sweating stage. Constipation must be avoided and sodium or magnesium sulphate should be administered regularly.

The specific drugs include quinine, plasmoquine and atebrin. Neosalvarsan can be used with advantage in resistant cases of *P. vivax* infection, but it exerts little effect on *P. falciparum*.

Quinine. Quinine remains the sheet anchor of malarial therapy. During an acute attack it has a less dramatic effect on malignant tertian malaria than on either benign tertian or quartan, but relapse is not so frequent. The drug acts on the schizonts and allays clinical symptoms, but does not kill either the gametocytes or the sporozoites. A number of different preparations are available including the hydrochloride, bihydrochloride, bisulphate and sulphate. There is no agreement regarding the optimum dosage and duration of treatment, but 10 grains thrice daily for the first week, followed by 10 grains twice daily for two weeks, thereafter 5 grains night and morning for three weeks is a reasonable compromise. With the exception of bihydrochloride of quinine, which can be given in non-sugar-coated tablets by the mouth, quinine should be administered in solution. The bisulphate can be readily dissolved by the addition of hydrochloric acid. Deafness and tinnitus may temporarily follow the administration of quinine in larger dosage and is a useful indication to its absorption. Owing to its solubility the bihydrochloride is used for both intramuscular and intravenous injection, the dosage being 10 grains and the concentration 1 grain to each cubic centimetre. Intravenous injections are superior and leave no after-effects, provided the quinine is adequately diluted and injected slowly. It is particularly useful (1) where vomiting is excessive; (2) in obstinate cases where quinine is ineffective *per os* through malabsorption or other causes; (3) in such grave types as cerebral or algid malaria where its speedy administration is essential to save life. Idiosyncrasy to quinine may manifest itself in severe erythematous and urticarial rashes and the usual toxic effects such as tinnitus, deafness, amblyopia, visual and gastric disturbances. Children bear quinine well and exhibit relatively greater tolerance than adults. For an infant of one year, 5 grains need not be regarded as excessive. In malarial countries it is sound practice to administer quinine during the puerperium and before operation or anaesthesia. As a general rule, quinine in adequate dosage reduces the fever in thirty-six to fifty-six hours, but occasionally cases are encountered which prove refractory even to intravenous quinine.

Plasmoquine. This drug—a methoxy-quinoline derivative—appears to have little effect on schizonts in malignant tertian malaria, though it destroys the gametocytes. In benign tertian malaria it probably acts on both sexual and asexual forms. The drug is best given in tablet form combined with quinine as quino-plasmoquine. Each tablet contains 0.01 gram ($\frac{1}{8}$ grain) of plasmoquine and 0.3 gram (4 grains) of quinine sulphate, two tablets being given thrice daily after food for six days. A clear interval of four days is allowed and a similar course readministered; four or five such courses are advocated. Toxic symptoms include nausea, vomiting, headache and a bluish discoloration of the skin due to methæmoglobinæmia.

Atebrin. This compound is a synthetic alkylamino-acridin derivative which

is administered in tablet form in a dosage of 0.1 gram after food, thrice daily, for five to seven days. Like quinine, it acts on the schizonts and compares favourably with that drug in ridding the blood of parasites, relieving symptoms and preventing relapses. Intestinal pain, troublesome dreams and transient yellow tinting of the skin may follow its administration, but serious toxic manifestations are infrequent; patients often prefer it to quinine owing to the short period over which it is administered. It is particularly valuable in quinine idiosyncrasy and blackwater fever, for unlike quinine and plasmoquine it never appears to precipitate hæmoglobinuria. Atebrin mucinate (0.125 gram = 0.1 gram of atebrin) has recently been introduced for intramuscular injection and has been widely used in the Ceylon epidemic, but the general consensus of opinion is that it has not proved satisfactory for dispensary work though efficacious in hospital patients. During convalescence iron may be given in full dosage in the form of Pil. Ferrous Carb. after meals, grains xv being taken three times a day, or as ferri et ammonium citras, grains xxx t.d.s. p.c. Malarial patients should be specially advised against cold baths, bathing, chill, over fatigue and taking alcohol to excess, as these are the factors which precipitate relapse in latent cases.

BLACKWATER FEVER

(*Malarial Hæmoglobinuria. Hæmoglobinuric or Melanuric Fever*)

Blackwater fever results from one or more intravascular hæmolyses in the course of chronic malignant tertian malaria, leading to rigor, fever, backache, vomiting, jaundice, anæmia, hæmoglobinæmia, hæmoglobinuria and perhaps anuria. A lytic substance originating from a metabolic breakdown is probably responsible.

Ætiology. Blackwater fever occurs on the western and eastern coasts of Africa, Nyassaland, Uganda, the Sudan and other parts of tropical Africa; in Madagascar, in the Duars, the Terai and the Jeypore Hill tract in India; in Palestine, Macedonia, Italy and Greece; in the Southern United States, Central America, Panama, Venezuela, Guiana and New Guinea. Invariably it originates in heavily infected or hyper-infected endemic zones of malignant tertian malaria and most frequently occurs after one to five years' residence. Where a patient recovers, recurrent attacks are not uncommon. Adults and children are both susceptible, but native populations may enjoy immunity where European residents and imported natives develop the condition. There is almost invariably a history of chronic malaria, for which quinine has generally been taken at irregular intervals. The exciting causes precipitating an attack are (1) the administration of quinine; (2) chill; (3) over-exertion. Quinine and plasmoquine may both precipitate attacks and possibly they do this through the quinoline ring which is common to both compounds. Cases, however, occur in which no quinine or other drug has been administered and a number of cases have been encountered during pregnancy.

Morbid Anatomy. The post-mortem findings are those of severe hæmoglobinuria engrafted on clinical malaria. The liver is soft and enlarged, the bile thick and tarry, the spleen is much increased in size with diffuent pulp and the kidneys are congested, dark and swollen. Hæmosiderin, giving a Prussian blue reaction for free iron, is found in the liver, kidneys and spleen and malarial pigment is present in the different viscera though not in as large amounts as one would anticipate. The kidneys show cloudy swelling, toxic degeneration and disintegration of the cells of the convoluted tubules, while eosinophilic granular *débris* blocks the lumina of the tubules. There may be cloudy swelling and central necrosis of hepatic cells in the liver lobules, while malarial pigment is generally demonstrable in the Küpffer cells. Jaundice is almost invariably present.

Clinical Pathology. At the beginning of a paroxysm in blackwater fever malarial parasites are frequently demonstrable, but after the second day they

tend to disappear and are generally absent at autopsy. The *urine* varies in colour from port-wine to porter and contains oxyhæmoglobin, generally methæmoglobin and also urobilin in excess. Albuminuria is invariable, but bile is noted only in the most severe cases. The centrifuged deposit is composed of a brown granular *débris* and granular casts; red blood corpuscles are scanty or absent. The *plasma* contains both oxyhæmoglobin and methæmoglobin which is the predominant pigment. Recently a new pigment (53) allied to methæmoglobin has been encountered which fails to reduce with Stoke's reagent and does not appear in the urine. Hæmobilirubin is greatly increased, the indirect van den Bergh varying from 5 to 85 units, but direct immediate and biphasic reactions are only found in gravely ill patients with toxic necrosis of the liver. Polyuria may be present or *renal involvement* may lead to oliguria and in some instances to anuria with urea retention, the blood urea rapidly rising to as much as 450 mg. per 100 c.c. before death. The blood urea is markedly increased, the excess being derived partly from destroyed corpuscles and partly through urea retention. Even in non-fatal cases it may reach 450 mg. per 100 c.c. Renal acidosis may develop; under these circumstances the CO_2 combining power of the plasma is markedly lowered, the serum calcium decreased and the blood phosphorus increased. The *anæmia* is normocytic in type and a rapid decrease in the red cell counts follows the onset of hæmolysis, of which there may be several distinct bouts. In severe cases 1,000,000 to 2,000,000 red corpuscles per c.mm. may be lost over-night (see Plate 66).

In blackwater fever the hæmolytic agent appears first to lyse the corpuscles and later to convert the liberated oxyhæmoglobin into methæmoglobin, acting in this respect as an oxidising agent (53). Both pigments appear in the plasma and when they reach a sufficient concentration the renal threshold is passed and they are excreted as such in the urine. If the urine be acid in reaction, oxyhæmoglobin which has filtered through the glomerulus is liable to be converted into methæmoglobin and acid hæmatin. Precipitation in the tubules results, causing blockage. Another factor—toxic degeneration of the secretory epithelium of the convoluted tubules—is, however, quite as important in causing the anuria. Both the quantity of blood lysed and the rapidity of its hæmolysis have an important bearing on the capacity of the kidney to recover, and should the amount hæmolysed exceed 540 c.c. within the half-hour, irreparable damage with fatal anuria appears to result. Only 10 per cent. or less of circulating blood pigment appears in the urine; the remainder has to be dealt with by the reticulo-endothelial cell system, with resulting hæmosiderosis, hyperbilirubinæmia and pleocholia.

Symptoms. As a rule, patients think there is an ordinary attack of malaria impending, for which they take quinine. Generally, within a few hours, but sometimes not for days, a rigor and pain in the loins develop, but in cases of less severity the first indication may be the passage of reddish-coloured urine. Following the rigor there is invariably a rise of temperature, which is accompanied or followed by nausea, epigastric discomfort, vomiting and anæmia. The urine soon becomes port-wine or porter coloured, though it may be reddish at first. Jaundice appears within a few hours of onset and is well-established by the second day. The pulse is rapid and at onset the blood pressure is markedly decreased, the systolic reading being 70 to 90 millimetres of mercury. Later, as the shock of the first intravascular hæmolysis passes off and the kidneys become implicated, the blood pressure rises. Headache and photophobia may be severe. As the anæmia increases the patient develops great restlessness and anxiety, the skin becomes pallid, the extremities cold and the pulse rapid and thready. Hiccough, which is almost constant in severe cases, is not incompatible with recovery, but like Cheyne-Stokes respiration it has a sinister significance. Abdominal examination reveals tender enlargement of the spleen and liver and there is often localised tenderness over the gall bladder which is tensely distended

with bile. During the attack, the spleen undergoes a decrease in size, attributable to expulsion of reserve blood to meet the anoxæmia. The temperature at onset resembles a malarial paroxysm and generally attains its maximum height on the first day; subsequently the fever may be either remittent or intermittent, and frequently reaches the normal in three or four days' time, though it may be prolonged for as long as a fortnight. Hyperpyrexia with temperature of 110° F. may precede death. After the hæmoglobinuria has ceased, post-hæmoglobinuric fever may appear and persist for several days. Apart from the average case as above described, several different clinical types are described: (1) *fulminating* types which die in from thirty-six to seventy-two hours as the result of toxæmia or anoxæmia; (2) the *anuric* type, which commences with severe symptoms, catheterisation showing only a small quantity of highly albuminous, perhaps bile-stained, urine, followed later by complete suppression with a normal or sub-normal temperature; this condition may last a week or longer before death occurs; (3) *continuous* or *intermittent* type of hæmoglobinuria; the temperature persists and hæmoglobinuria may be either continuous or remittent, several distinct bouts of hæmolysis occurring during the period; post-hæmoglobinuric fever may follow; (4) *hæmorrhagic* type; here cases may develop skin hæmorrhages, hæmatemesis or melæna.

Course and Complications. The complications include hæmolytic anæmia, anuria, post-hæmoglobinuric fever and biliary colic; pigment calculi and cholecystitis are occasional sequelæ. According to Ross (54), about 10 per cent. of the cases relapse during the course of an attack. Unfavourable features include intense jaundice, anuria, hyperpyrexia and the appearance of bile in the urine. Dyspnœa, Cheyne-Stokes respiration and a fall of the red cell count to 1,000,000 per c.mm. or less are ominous features, and death is inevitable under these circumstances unless anoxæmia be combated by blood transfusion. The mortality rate is about 30 per cent.

Prevention. The prevention of blackwater is the prophylaxis of malignant tertian malaria. Quinine, if taken prophylactically, should be taken continuously in 5-grain doses daily during the period of residence in an endemic area of blackwater fever. As both quinine and plasmoquine are known to precipitate attacks and atabrin appears free from this danger, patients who have previously had blackwater fever should receive only atabrin for malaria during the febrile stage, followed by quinine later where necessary.

Treatment. Since the hæmolysis itself cannot be controlled the most rational procedure is to treat complications as they arise and combat the known causes of death which are: (1) anæmia, anoxæmia and heart failure; (2) toxæmia; (3) urinary suppression. One is justified in moving a patient only if it places him under better conditions for treatment. The patient must be kept continuously in bed and nursed in the recumbent posture; under no circumstances should he attempt to sit up or do anything for himself. With patients suffering from shock with low blood pressure it is immediately advisable to elevate the foot of the bed, supply hot bottles and bandage the limbs. Fluid in large quantity should be given by the mouth, and if necessary by the rectum and intravenously. Barley water, fruit juices and glucose are allowed, and later milk, junket, arrowroot, custard and Benger's food. Proteins are restricted well into convalescence or until renal function is normal. Vomiting often is troublesome and gastric lavage with bicarbonate of soda may prove valuable. The urine should be alkalisied as rapidly as possible by the administration of citrate and bicarbonate; should this fail in its objective 1 pint of doubly distilled water containing 150 grains of bicarbonate of soda solution may be injected intravenously and repeated if necessary. Owing to the liability of converting the bicarbonate into the toxic carbonate during sterilisation by heat, it is better to add bicarbonate powder after the distilled water has cooled, unless it be possible to sterilise the bicarbonate solution by filtration. For anuria, 1 to 2 pints of an

isotonic 5 per cent. solution of glucose are used or smaller quantities of hypertonic glucose (10 per cent. to 20 per cent. solution) may be substituted. Heat and dry cupping should be applied to the loins and mild diuretics like caffein citrate may be given. The bowels should be kept open with a saline purge. Blood transfusion may be necessary in severe cases after hæmolysis has ceased, but it should be given to all gravely anæmic cases during the hæmolytic period where the counts fall below 1,500,000 cells per c.mm., and especially if tachycardia, restlessness, dyspnœa and Cheyne-Stokes respiration be present. Transfusion can be given with absolute safety in polyuric cases, but where oliguria is marked or anuria has set in it should only be given for grave anæmia. Where parasites persist atebirin may be given with safety. Iron should be given in full dosage during convalescence, commencing about the fourteenth day.

Leishmaniasis comprises a group of diseases caused by parasites of the genus *Leishmania*, and includes kala-azar due to *Leishmania donovani*, Mediterranean or infantile kala-azar caused by *Leishmania infantum*, oriental sore due to *L. tropica*, and espundia or American leishmaniasis due to *L. brasiliensis*. The various *Leishmania* affecting man are morphologically indistinguishable (55), and little assistance is obtained from animal inoculation. Noguchi (56) found three distinct serological types—*L. donovani*, *L. tropica* and *L. brasiliensis*; the agglutinating reactions with cultures of *L. donovani* and *L. infantum* were identical. Recently Penna (57) has described the presence of visceral leishmaniasis in Brazil, the parasite differing from the *Leishmania* form of *Trypanosoma cruzi* in sections of the liver, but whether it is identical with *L. donovani* has not yet been determined.

KALA-AZAR (Plate 67, 4, p. 1053)

(Black Fever)

This is a specific disease associated with splenomegaly, hepatomegaly, emaciation, irregular fever and anæmia caused by *L. donovani*, which can be demonstrated in the peripheral blood or by splenic puncture. The insect vector is almost certainly *Phlebotomus argentipes*.

Ætiology. Kala-azar is found in India, Assam, North China and the Mediterranean littoral, where children are mainly affected; more rarely it occurs in Indo-China, the Sudan, Abyssinia, Mesopotamia and Russian Turkestan. Both Europeans and natives contract the disease. In the human body the parasite occurs as a small, oval structure some 2 to 5 μ long and 1 to 2 μ in breadth, containing a macronucleus or trophonucleus staining bright red and a micronucleus or rhizoplast which is rod-shaped, staining a deep purple red with Romanowsky's stain. Blood obtained by venous puncture or splenic juice generally contains the parasites; these can be cultivated on rabbit blood agar (N.N.N. medium) kept at room temperature (20° to 25° C.) for fourteen days provided bacterial contamination be avoided (see Plate 67). During this period the parasite develops a flagellum and centrosome at one end and a central macronucleus—undoubted evidence that under natural conditions it undergoes development in some insect vector which is almost certainly the sand fly. If sand flies be fed on kala-azar cases, leptomnad forms develop which are capable of producing the disease on injection into hamsters; to date, however, transmission has rarely been attained through the actual bite of experimentally infected sand flies. The Mediterranean form of kala-azar especially affects children. The dog is the natural host and transmission again is by sand flies.

Pathology. *Leishmania donovani* bodies are found in the reticulo-endothelial cells, especially of the liver, spleen, lymphatic glands and the bone marrow, where they multiply and eventually rupture; subsequently they are taken up by the phagocytic cells. They have also been found in the kidneys and intestinal

submucosa. At post-mortem, wasting is marked, and effusions into the serous sacs not infrequent. Early the spleen is soft and pliable, later it becomes hard and fibrous. Perisplenitis, thickening of the capsule and infarction is by no means uncommon. The liver is firm, its capsule thickened, and a nutmeg appearance and fatty degeneration are common. Cirrhosis may eventually result. The parasites are found in large numbers in the Küpffer's cells. The marrow in the long bones is red and soft, due to hyperplasia, and the mesenteric glands are swollen and may show central necrosis. The heart is flabby and dilated, while ulceration may involve the small or large bowel.

Symptoms. Cases may occur a year or more after exposure to infection, but generally the incubation period varies from one to four months. The onset is insidious or sudden with fever which may be mistaken for typhoid or malaria. The temperature may be irregular, remittent or intermittent. Sometimes there is no fever during the day, but a rise occurs later; in others there is a double daily rise in the afternoons and evenings. The skin may show a deepening colour with pigmentation and loss of hair. The liver is palpable in nearly 90 per cent. of cases, presenting a sharp lower border. Splenomegaly is the rule, but during the first month or two it may not be palpable; generally at this stage it is obviously enlarged and feels soft but not tender; later it may attain huge dimensions, conveying a sense of hardness to the palpating hand. The appetite is good but the digestion poor and this in itself may lead to diarrhoea. Night sweats are common. A moderate degree of anæmia with rapid loss of weight and cachexia frequently develops. There may be palpitation, dyspnoea, oedema of the extremities and occasionally puffiness of the face. The blood pressure is low, systolic readings often being below 100 mm. mercury. Congenital cases have been described where an infected mother has transmitted the disease directly to the foetus. *L. donovani* may be demonstrated in thick blood films, in smears from the liver or spleen or by blood culture. *Splenic puncture:* the patient should be recumbent and the skin sterilised by tincture of iodine; an area is selected an inch or so below the costal margin about midway between the anterior and posterior margin of the spleen. If large enough, an assistant may hold the organ in position to prevent movement and the patient should be instructed to hold the breath when the needle is inserted. After the skin has been anæsthetised, a needle $1\frac{1}{2}$ inches in length is inserted firmly into the spleen in a backward and upward direction, and the attached syringe aspirated. Better results are obtained if the splenic juice contains a minimum of blood. It is essential always to examine the peripheral blood for leukaemia before puncturing the spleen, as fatal hæmorrhage may otherwise result, also to watch the patient for two or three hours after this procedure. Slides are prepared by smearing a drop of the splenic juice on a clean slide, letting this dry and subsequently staining with Giemsa's or Leishman's stain.

The *Aldehyde Test* is of great value and has largely replaced spleen puncture in the large kala-azar clinic at the Calcutta School of Tropical Medicine. Napier's technique is as follows: About 5 c.c. of blood are taken from the median basilic vein and allowed to clot; 1 c.c. of the supernatant serum is subsequently removed with a pipette and 2 drops of commercial formalin are added to it in a small test tube, which is shaken and left at room temperature. If the reaction be positive, a white opacity develops within one to two minutes, and within half an hour set-like blancmange, so that the tube can be inverted without spilling. Mere jellyfication has no significance, the diagnostic feature being an opaque solidification like the white of a hard-boiled egg. About 80 per cent. of cases give positive reactions as against about 90 per cent. on splenic puncture. The aldehyde test is generally negative during the first three months of the illness.

Blood Picture. The blood changes include anæmia, leucopenia and reduction in the platelet count. The hæmoglobin may be reduced proportionately to the fall in erythrocytes so that the colour index approximates to 1; in other cases it varies from 0.7 to 0.8. The anæmia itself is generally of moderate intensity, but

in severer cases the blood picture shows anisocytosis, poikilocytosis, polychromasia and normoblasts. It has been attributed to the crowding out of the erythroblastic marrow by proliferating reticulo-endothelial cells which are heavily parasitised. Leucopenia is extremely characteristic and counts of 2,000-4,000 per c.mm. are common. There is a relative increase in lymphocytes and monocytes with a decrease in neutrophiles and eosinophiles. The coagulation time may be extended while the globulin is raised and the serum albumin, sugar and calcium decreased; euglobulin increases at the expense of the pseudoglobulin fraction.

Complications and Sequelæ. Diseases like influenza, pneumonia and tuberculosis commonly cause death. Otitis media and cancrum oris may be encountered, especially in children. During treatment with antimony compounds, agranulocytosis may develop, and probably the tendency to cancrum oris as well as susceptibility to secondary infection is related to the depressed condition of the leucoblastic marrow as indicated by the leucocyte counts. Epistaxis, bleeding from the gums, melæna and purpura sometimes supervene, and diarrhœa with or without muco-sanguineous stools is frequent; the latter finding, however, should always suggest dysenteric infection (58). Chronic splenomegaly, associated with severe anæmia, and hepatic cirrhosis, with or without ascites and demonstrable parasites, are included amongst the sequelæ. Jaundice not infrequently appears within three months of treatment. Post kala-azar dermal leishmaniasis may also occur, beginning within a year of treatment as areas of pigmentation, followed by papulomatous nodules in which *L. donovani* are found. The parasites are confined to the skin and puncture fails to reveal them in either the spleen or liver. Occasionally dermal lesions develop in patients giving no history of previous kala-azar infection.

Diagnosis. Kala-azar has to be differentiated from the fevers associated with splenomegaly, and these include, in order of their importance, chronic malaria, undulant fever, typhoid and the para-typhoid fevers. In children Mediterranean kala-azar needs to be differentiated from certain blood diseases such as Cooley's anæmia commonly encountered in Greece, von Jaksch's anæmia and acholuric jaundice, and it should be remembered that parasites are less common in the peripheral blood than in Indian kala-azar. In both varieties laboratory confirmation should be sought.

Prognosis. The mortality rate in untreated patients is about 90 per cent.; the disease lasts from one to two years in chronic cases. Modern therapy generally results in cure, but a careful watch must be kept for the onset of agranulocytosis which requires immediate injections of nucleotide K.96.

Prevention. As the sand fly is the probable vector, measures directed to its destruction are indicated. The abandonment of infected houses, segregation and treatment of people who have acquired the disease are measures which have proved efficacious in India.

Treatment. General treatment includes rest in bed during the febrile stage, a light nourishing diet adequate in vitamins with iron tonics for the anæmia. Cardiac stimulants such as digitalis are indicated in advanced cases. The old treatment with trivalent antimony compounds like tartar emetic has been replaced by pentavalent antimony derivatives which include neostibosan or von Heyden 693, urea-stibamine, neostam and stibosan von Heyden 471. With neostibosan an initial dose of 0.1 to 0.2 gramme may be given, and subsequently this should be increased to daily injections of 0.3 gramme over a period of eight to twelve days; debilitated patients may require smaller dosage. Toxic features include nausea, vomiting, diarrhœa, giddiness, toxic hepatitis with jaundice, and occasionally an anaphylaxis-like condition with cardio-vascular collapse, urticaria and œdema of the subcutaneous tissues of the face. Insufficiently treated cases relapse, and occasionally patients need larger doses and more prolonged courses of treatment. If agranulocytosis with cancrum oris appears injections of

nucleotide K.96 should be given immediately. Favourable features include a decrease in the size of the spleen, disappearance of the fever, increase in weight, re-establishment of a normal leucocyte count and a negative splenic puncture.

Children affected with Mediterranean kala-azar require more prolonged treatment and relatively a larger dosage of neostibosan or urea-stibamin to cure the condition.

ORIENTAL SORE

(*Tropical Sore. Bagdad Boil. Delhi Boil, etc.*)

An infective granuloma caused by *Leishmania tropica* involving the skin and subcutaneous tissues on exposed parts of the body.

Ætiology. The disease has a widespread distribution in India, the North-West Frontier, Mesopotamia, Arabia, Persia, parts of Africa, Spain, Italy and Greece. Being a disease of towns its endemicity has given rise to many synonyms. Though absolute proof has not yet been obtained, the remarkable development of *L. tropica* into virulent flagellates from the mid-gut to the proboscis of sand flies, like *Phlebotomus papatasi* and *P. sergenti*, suggests them to be the natural vectors of oriental sore. Wenyon, after experimental auto-inoculation, waited six months before the sore made its appearance. Dogs, cats and guinea-pigs are susceptible.

Pathology. The pathology is that of an infective granuloma. There is atrophy of the epidermis, infiltration of the corium and its papillæ with plasma cells, lymphocytes and endothelial cells containing the parasites.

Symptoms. The incubation period varies from a few weeks to six months. An itchy, red papule first appears which develops into a sort of blind boil or becomes covered with yellow crusts and forms a chronic indolent ulcer. The ulcer itself has a granulation tissue base which exudes a thin pus, and possesses well-defined, rounded edges. The sores are particularly common on the face, hands, wrists, feet and legs, and may be single or multiple; on healing they leave an unsightly scar.

Diagnosis. This is made on the history, the geographical location of the patient, the characteristic local lesions and the isolation of the parasite. To demonstrate *L. tropica*, the edge of the ulcer should be punctured with a dry glass pipette and the material so obtained inoculated on to rabbit blood agar (N.N.N. medium). Smears should also be made and stained with one of the Romanowsky stains, as *L. tropica* can frequently be demonstrated within the endothelial cells.

Prognosis. If untreated the condition may last from six to eighteen months; and as a rule the patient appears subsequently immune to further infections. The ulcers may be secondarily infected with bacteria, but severe sepsis rarely develops and the condition itself is practically never fatal.

Prevention. Active measures should be directed to the extermination of sand flies and their breeding grounds.

Treatment. Tartar emetic may be given intravenously as for schistosomiasis (p. 1070), a total course of 20 to 30 grains being advisable. Neostibosan has also been employed successfully. Injections of 1 c.c. of berberine sulphate ($\frac{1}{2}$ grain to 1 c.c.) two or three times a week have been utilised with benefit. Vaccines made from cultures of the parasites have been favourably reported on. The application of carbon dioxide snow for five to thirty seconds every ten days and X-ray therapy are especially useful. Ointments containing methylene-blue, iodoform and tartar emetic have been employed; the latter is used in a strength of 1 to 2 per cent., but unfortunately local sloughing and much pain result.

American Dermal Leishmaniasis. (*Espundia; Forest Yaws, etc.*) This is an infective granuloma caused by *Leishmania brasiliensis* which involves the skin and not infrequently the buccal and nasal mucous membranes, the lymphatics and lymph glands.

Ætiology. The geographical distribution is limited to Brazil, British and Dutch Guiana, Venezuela, Peru, Paraguay and Bolivia. It is encountered

amongst people living in forests, like woodcutters, but the insect vector is unknown.

Symptoms. The incubation period is from six to ten weeks. Itching papules appear which generally involve the skin and may either develop into blind boils or break down and ulcerate, forming fungoid granulations and large ulcers. Sometimes the marginal membranes of the mouth and nose are implicated, while later the nasal septum and larynx may be involved. General features such as pyrexia, joint pains and pulmonary symptoms develop, and the disease runs a chronic course extending over many years. Untreated patients generally die from intercurrent disease.

Diagnosis. The condition has to be differentiated from leprosy, tuberculosis, syphilis, gangosa and rodent ulcer, and this is best done by demonstrating the parasites in scrapings from the edge of the ulcers or by culture on N.N.N. medium as in *L. tropica* infections.

Treatment. A full course of 40 grains of tartar emetic should be administered intravenously, while other lines of treatment similar to those outlined for oriental sore and kala-azar are applicable.

Trypanosomiasis comprises a widespread group of diseases, caused by flagellate parasites of the genus *Trypanosoma* occurring in the blood and tissues of vertebrates. In Africa man is infected by *T. gambiense* or *T. rhodesiense*, and in South America by *T. cruzi*. *T. brucei*, which causes nagana affecting cattle, wild game, dogs and horses, is generally believed to be identical with *T. rhodesiense*.

AFRICAN TRYPANOSOMIASIS (Plate 67, 1, 2)

(Sleeping Sickness)

African trypanosomiasis is transmitted by the bite of tsetse-flies infected with *T. rhodesiense* or *T. gambiense*. Clinically it is characterised by irregular fever, circinate erythematous rashes, enlargement of the lymph glands and spleen and rapid pulse. Later the nervous system becomes involved with mental and physical degeneration, lethargy, tremors, shuffling gait, convulsions, coma and death.

Ætiology. Sleeping sickness must not be confused with sleepy sickness, the lay term for encephalitis lethargica. It is confined to tropical equatorial Africa, including West, Central and East Africa, and limited geographically to localities where the tsetse fly abounds. Areas particularly affected are the Congo, Uganda, Rhodesia and Nyasaland. Both sexes and people of any race and age are susceptible; Europeans suffer severely. Though the disease has long been known, it was not until Uganda was invaded in 1900 and its population greatly reduced that serious attention was paid to it. Two species of trypanosomes are recognised, *Trypanosoma gambiense* and *T. rhodesiense*, though they are indistinguishable in human blood and give rise to similar clinical manifestations. The trypanosome (see Plate 67, Figs. 1 and 2) is an elongated flagellate measuring from 18 to 25 microns in length and 2 to 2.8 microns in breadth. Centrally situated, there is a large oval nucleus (*trophonucleus*), while at the blunt posterior extremity one finds a small chromatin mass (*parabasal body*), and adjacent to it a smaller structure (*blepharoplast*) from which proceeds a flagellum. This flagellum runs along the free border of an undulating membrane to the anterior extremity of the organism and projects some distance beyond it. Parasites are found in the blood and lymph glands during the febrile stage and in the cerebro-spinal fluid later, while the disease may be produced in monkeys by inoculation of this fluid. The only means of differentiating the two species is to inoculate infected blood into white rats when post-nuclear forms develop if *T. rhodesiense* be present. Tsetse flies take up trypanosomes when sucking blood from man; the parasites multiply in the gut and pass forward to the salivary ducts and salivary glands where development proceeds. Within three to seven weeks the glossinæ become

infective and remain so for life. *T. gambiense*, the Central African type, is transmitted by *Glossina palpalis*, which may acquire its infection from wild game in the vicinity of lakes and rivers frequented by this fly. *T. rhodesiense* is spread by another fly, *G. morsitans*, which inhabits arid country and probably acquires its infection from wild game also, Bruce regarding it as identical with *T. brucei*. Both glossinæ bite in the day time, but as they have different habitats prophylactic measures for their eradication vary considerably.

Pathology. The lymph glands draining the bitten area are first implicated, especially those in the neck and groin. They become swollen, inflamed and perhaps hæmorrhagic, undergo degeneration changes and chronic fibrosis. Splenomegaly also results from lymphoid hyperplasia, endothelial proliferation and fibrosis, while the capsule of the organ is often thickened. In the later stages trypanosomes involve the nervous system, producing microscopic changes resembling meningo-encephalitis and meningo-myelitis. Lymphocytic infiltration of the perivascular system is characteristic (Mott), and trypanosomes are found in the intercellular spaces of the brain and cord (York). Neuroglial cell overgrowth, diffuse glial proliferation and chromatolysis of the nuclei of the ganglion cells may be found.

Symptoms. The incubation period is from one to three weeks, but may be sometimes prolonged for some months. In many respects the disease resembles syphilis. Three stages may be recognisable, i.e., the local lesion, a febrile stage and a cerebral stage. (1) *Local Features.* The bite of the infected glossina may cause inflammatory reaction lasting some days, and occasionally a delayed anaphylactoid type of local lesion with marked erythema and widespread indurated swelling of the skin and subcutaneous tissue results some weeks to ten days after the bite. (2) *Febrile Stage, or Trypanosome Fever.* The patient develops attacks of fever lasting for a variable period. The temperature is low in the morning, higher at night and of an irregular, remittent or intermittent type. Periods of apyrexia may last for weeks. The pulse is rapid and of low tension, generally about 100 to 120 per minute, and a high rate persists even during the apyrexial periods. There is an increase in the respirations to twenty to thirty a minute. Erythematous rashes also appear, circinate in form, which involve mainly the trunk, and localised puffiness or œdema of the face, legs and feet may occur. The skin is often irritable and dry. Enlargement of the posterior cervical glands (Winterbottom's sign) is a characteristic feature, while the epitrochlear, axillary and supraclavicular may also be involved; they are enlarged, elastic and soft, but not tender to the touch; periadenitis is not present. The spleen is frequently palpable and deep hyperæsthesia may develop over long bones like the tibia, a peculiarity being the latent period which intervenes before pain is felt (Kerendel's sign). (3) *Cerebral Stage.* Periods of several months may elapse before the central nervous system becomes involved, and prior to this spontaneous cure may occasionally occur. Once cerebral symptoms develop death invariably follows within a year or so in the absence of treatment. The patient at first lacks concentration and is disinclined for work; he complains of headache, drowsiness and insomnia, associated with physical weakness, loss of weight and enlargement of the lymph glands. The expression is vacant, the upper eyelids droop, the lower lip falls so that the teeth are exposed, and the lips become dry and cracked. In the intermediary phase, laziness and emotional instability increase. The patient drops off to sleep even in tropical sunlight or when eating. The face is puffy, the countenance apathetic and morose. Speech is mumbled and slow, the gait shuffling and the tongue, lips and hands become tremulous. Reflexes are exaggerated and Romberg's sign is present. The sufferer walks with difficulty, supported by a stick. The temperature is raised a little in the evening and the pulse is often very rapid. In the final stages these symptoms become accentuated. Muscular weakness is extreme, saliva drops from the mouth, the patient lies persistently in one position, either flat on the ground face down, or

curled up on one side, or forward in a kneeling posture. He eats only what is brought to him and stops eating while food is still in the mouth. Bed sores form and flexure-contractions develop. There may be chorea-form spasms and twitchings, rapid wasting and diarrhoea, while papulo-vesicular and pustular eruptions are not uncommon as the patient becomes bedridden. Convulsions, coma or mania may precede death. The terminal picture is not unlike that of general paralysis of the insane.

Complications. Abortion and still-births are not infrequent, while intercurrent diseases, like dysentery and pneumonia, are often fatal. Keratitis and iridocyclitis may develop and both tryparsamide and atoxyl may cause optic atrophy when given in full dosage.

Diagnosis. History of residence in an endemic area is most important, and in these circumstances any irregular fever, especially if associated with enlargement of the cervical glands, should arouse suspicion. Trypanosomes are most easily demonstrated in fluid obtained by gland puncture in the posterior triangle of the neck. The gland chosen must be aspirated into a dry syringe, and according to Broden 87 per cent. of cases show trypanosomes. They may also be found in thick blood films, or in smears from centrifuged fluid. Inoculation of white rats with blood or an emulsion of gland substance is a valuable procedure as it enables the two species to be differentiated. In the later cases lumbar puncture should always be performed. The cerebro-spinal fluid is under increased pressure, contains an excess of globulin and lymphocytes, and not infrequently medium-sized mononuclear cells. The cell count varies from 15 to 1,000 cells per c.mm., but even after centrifuging the cerebro-spinal fluid and animal inoculation trypanosomes are often not demonstrable.

Prognosis. The disease lasts from two to fifteen months, and once the central nervous system is involved it is invariably fatal unless treated. The outlook is very hopeful in *T. gambiense*, provided treatment be instituted before the central nervous system is involved; after this it is more doubtful and should patients relapse with nerve symptoms the prognosis is bad. *T. rhodesiense* causes a far more virulent infection. The death rate amongst Europeans is less than amongst natives—probably because they are treated earlier and under better conditions and are less liable to intercurrent infections.

Prevention. The destruction of big game and the depopulation of endemic areas have proved unsatisfactory, and measures directed to extermination of glossinæ and the avoidance of their bites are to be preferred. Removal of all undergrowth and bush for a distance of 15 feet around lakes and rivers is useful in the case of *G. palpalis*, and ingenious fly traps have recently been evolved which are very efficient. Shorts should never be worn in tsetse-fly areas, the clothes should be white and gloves and veils used where feasible. Whenever possible travelling should be done at night.

Treatment. The general health of the patient must be built up in every way, intercurrent infections eliminated and a nourishing diet, adequate in vitamins, prescribed. A number of drugs exert a beneficial and, in some cases, a curative effect in this disease. (1) Tartar emetic. This is given intravenously three times a week, beginning with $\frac{1}{2}$ grain and working up to 2 grains in 10 c.c. of distilled water. As much as 60 grains may need to be administered. (2) Soamin or Atoxyl (sodium arsanilate). Intramuscular injections are given in a dosage of 3 grains twice weekly or 7 grains once weekly. (3) Germanin, or Bayer 205, is a complex organic urea compound, 1 gramme of which is injected weekly for ten injections. It is especially useful in sterilising the blood in early cases before the central nervous system has become involved, but unfortunately causes nephritis with albuminuria and casts, so that during treatment it is essential to keep the patient in bed on a milk diet. (4) Tryparsamide (N-phenylglycineamido-p-arsenate) is especially indicated where the central nervous system is implicated, and is given intravenously in weekly doses for ten to twelve weeks, commencing

with 1 gramme in the first week, 2 grammes in the second and 3 grammes weekly for the remaining period. Children receive relatively larger doses. The drug is toxic and may cause hepatitis with jaundice, arsenical dermatitis or optic atrophy; the latter may be suggested by pain in the eyes, lachrymation, photophobia and failing vision, and unfortunately many cases of total blindness have been recorded. During the treatment the discs should be carefully examined for early indications of optic atrophy.

SOUTH AMERICAN TRYPANOSOMIASIS (Plate 67, 3, p. 1053)

(Chagas' Disease. Brazilian Trypanosomiasis)

This disease occurs in Brazil and other parts of South America and affects children and adults of both sexes. It is caused by *Trypanosoma cruzi*, which is a short broad trypanosome about $20\ \mu$ in length, possessing a central nucleus and a large, ovoid, posteriorly situated kinetoplast (Plate 67, Fig. 3). The disease is transmitted to man by the bite of the reduviid bug, *Triatoma megista*. Trypanosomes are found in the peripheral blood during the first two or three weeks following infection; subsequently they assume a Leishmanial form within the cells of the viscera, where they undergo division and periodically pass back into the peripheral circulation.

Pathology. The Leishmanial forms are found in tissue sections of the voluntary muscles, myocardium and brain of man as well as in the testicles, ovaries, bone-marrow and supra-renals. In these situations they multiply, causing cell destruction and in the nervous system lesions resembling meningo-encephalitis and meningo-myelitis result. There is enlargement of the spleen, liver and lymph glands, and, according to Chagas, the thyroid is swollen, congested and even goitrous.

Symptoms. The incubation period is from seven to ten days. The acute type generally occurs in children under one year and is characterised by fever, splenomegaly, polyadenitis, puffiness and œdema of the face; symptoms of encephalo-meningitis may ensue with fatal results. The chronic disease includes cardiac and nervous types, with deranged cardiac rhythm and neurological features, including paralyses caused by intracellular invasion with Leishmanial forms of *T. cruzi*. Recent work has questioned the validity of thyroid involvement associated with this disease, Kraus attributing symptoms such as cretinism and myxœdema to endemic goitre and not to Leishmanial involvement.

Diagnosis. This is generally made in the laboratory. During the first two or three weeks trypanosomes may be found in the peripheral blood and are occasionally demonstrated in tissue juice following muscular puncture. The complement fixation reaction is stated to give a positive reaction in 87 per cent. of cardiac cases.

Treatment. Measures should be directed towards the eradication of the insect vector, *T. megista*. None of the drugs effective in African trypanosomiasis are efficacious here, so treatment is largely symptomatic and directed towards the system particularly involved.

AMŒBIC DYSENTERY

Amœbic dysentery is caused by an invasion of the large bowel by *Entamœba histolytica*, producing local ulceration and the passage of several stools daily containing brownish mucus or dark red blood. The colon is often thickened and tender, while complications including amœbic hepatitis and liver abscess are not uncommon.

Ætiology. Amœbic dysentery, caused by *Entamœba histolytica*, is mainly found in the tropics and subtropics, though sporadic cases may be encountered in temperate climates. Walker and Sellards (1913), when studying experimental infections amongst condemned prisoners in the Philippines, proved that *E. histolytica* was pathogenic to man, and *E. coli* a harmless commensal. People of

both sexes and any age may acquire the disease, though it is relatively uncommon in young children. Man becomes infected by swallowing the cysts of *E. histolytica* in water or in food which has been contaminated by carriers or infected faecal material conveyed by flies. In the duodenum and small intestine the cyst walls are dissolved by the pancreatic juice and the amœbulæ escape and subsequently invade the mucous membrane of the large intestine. The tissue-invading amœbæ which are present in faecal mucus are of large size, being 20–30 μ in diameter; they are actively motile and contain ingested erythrocytes. As the lesions begin to heal these large forms are replaced by pre-cystic amœbæ, while the tissue-invading forms are confined to the bowel wall. These pre-cystic amœbæ measure only 7–18 μ in diameter, are less actively motile and resemble *E. coli* in containing no red cells. The cysts of *E. histolytica* are met with in the faeces of carriers and chronic sufferers from the disease; they contain one, two or four nuclei and have characteristic chromidial bodies. Under the influence of the intestinal juices the four-nucleated amœba bursts through a small pore in the cyst wall and subsequently divides, giving rise to eight small amœbulæ, each of which ultimately develops into an adult *E. histolytica*.

Pathology. The tissue-invading amœbæ present in faecal mucus invade the surface epithelium between the gland crypts, causing superficial erosions, and subsequently burrow deeper into the connective tissues, producing gelatinous necrosis and sometimes thrombosis of adjacent venules; as the process extends small abscesses form which burst, producing superficial ulcers with undermined edges. Ultimately, large bottle-necked ulcers, an inch or more in diameter, filled with cell debris, mucoid material and amœbæ, may develop in the submucosa. Common sites for ulceration are the cæcum, ascending colon, sigmoid colon and the rectum; the process rarely, if ever, extends above the ileo-cæcal valve. Between the ulcers the intervening mucosa appears healthy, a state of affairs which is not encountered in bacillary dysentery. In some instances ulcers extend to the muscular coats or peritoneum; adhesions may form, and occasionally extensive sloughing and perforation lead to peritonitis. When the ulcers heal pigmented scarring of the mucosa results, and, if sufficiently deep, thickening and scarring on the peritoneal surfaces of the bowel may be observed.

Symptoms. The incubation period varies from three weeks to three months. The onset is insidious in at least 90 per cent. of cases. At first the stools are liquid and indistinguishable from an ordinary diarrhœa; as the condition progresses faecal material becomes mixed with brown mucus and degenerated blood, three to six such stools being passed daily. In 10 per cent. of cases the condition resembles bacillary dysentery, having a sudden onset with fever, abdominal colic and purging, associated with the passage of sanguineous, mucoid, brown stools. In the average case, however, constitutional disturbances are slight; there is little or no pyrexia, while headache, nausea and vomiting are absent. Colicky abdominal pain is characteristic, and tenesmus is present where the rectum is involved; dysuria and frequency of micturition may also be noted under these conditions. As the disease develops there is considerable loss of weight, the skin becomes dry and of an earthy-brown hue, and loss of appetite, dyspepsia and a mild or moderate anæmia of secondary type follow. On palpation the pelvic colon and sometimes the cæcum are thickened and tender. Sigmoidoscopy is invaluable. The first lesions appear as small superficial yellowish nodules, with scattered petechial hæmorrhages in the mucosa; later, painless, yellow ulcers, surrounded by a zone of erythema, appear, and if scrapings from the bases of these be examined the vegetative forms of *E. histolytica* are readily demonstrable. The mucosa between the ulcers appears normal. Occasionally a more generalised proctitis and colitis, similar to that observed in kittens, may be encountered; there is œdema and swelling of redundant mucosal folds which bleed readily on trauma, and large numbers of motile *E. histolytica* are found in the scrapings. Rarely an amœbic granuloma may occur in the rectum and pelvic colon which

simulates carcinoma ; from this it may be differentiated by microscopic section of tissue removed during sigmoidoscopy and by its rapid disappearance under emetine treatment. The blood may show some secondary anæmia ; only a slight leucocytosis of from 10,000 to 15,000 cells per c.mm. develops, and generally the neutrophiles are not increased above 75 per cent. unless some complication like hepatitis or abscess has supervened.

Course and Complications. Local complications include intestinal hæmorrhage, perforation with local abscess or peritonitis, post-dysenteric adhesions and amœbic appendicitis. Amœbic hepatitis and liver abscess are the commonest complications, while amœbiasis of the spleen, abdominal wall, seminal vesicles, testicles and brain have all been recorded. Clinically the latter simulates cerebral tumour.

The course of amœbic dysentery is essentially chronic and there is a marked tendency to both spontaneous recovery and relapse. A peculiar feature is the extraordinary latency of infection in certain patients. Contact carriers may give no history of dysentery, while patients with well-marked hepatitis or amœbic abscess may never remember having had any serious bowel disturbance.

Diagnosis. The differential diagnosis includes chronic bacillary dysentery, ulcerative colitis, bilharzia dysentery, ciliate dysentery caused by *Balantidium coli*, carcinoma and diverticulitis. Sigmoidoscopy, laboratory investigation of the excreta and X-ray examination may prove essential. Diagnosis is made by demonstrating large motile amœbæ containing red blood corpuscles in the faecal mucus in the early stages and the pre-cystic amœbæ and cysts in the stools of chronic cases and carriers. Several non-pathogenic amœbæ may occur in human faeces, and include *E. coli*, *Endolimax nana*, *Iodamœba butschlii* and *Dientamœba fragilis* ; considerable experience is required for their identification. Examination of scrapings of ulcers obtained during sigmoidoscopy often enables *E. histolytica* to be demonstrated in doubtful cases. The nature of the pathological exudate and the presence of Charcot-Leyden crystals may suggest, but by no means prove, the presence of an *E. histolytica* infection. X-ray examination after a barium enema is mainly of value in eliminating other diseases of the large bowel with mucoid stools.

Prognosis. In the absence of complications cases invariably recover with modern treatment, and most of them can be permanently cured. Occasionally intractable cases are encountered in which drugs fail to eradicate infection ; even so treatment does much to relieve symptoms and prevent the development of complications. Colonic perforations are generally fatal.

Prevention. Flies and human carriers are the main sources contaminating food and water, and it is particularly important to ascertain that people employed in the kitchen, such as cooks and waiters, are free from infection. Latrines should be well separated from kitchens and all food carefully covered with wire gauze coverings ; if possible bungalows should be kept fly-proof. Uncooked vegetables and fruit should be washed in permanganate solution before being eaten and drinking water boiled or chlorinated. In camps, latrines should be so constructed that the faeces are passed into vessels containing disinfectant and subsequently destroyed in an incinerator or by burial.

Treatment. Patients passing blood and mucus should be put to bed on a simple low residue diet and specific drugs administered. The curative properties of ipecacuanha were recognised before the various types of dysentery were differentiated. Rogers in 1912 demonstrated the specific action of one of its main alkaloids, emetine (59), in the treatment of amœbiasis. *Emetine* is a toxic drug which may poison the myocardium ; for this reason patients must be confined to bed when receiving emetine treatment. The alkaloid is injected subcutaneously or intramuscularly in a dosage of 1 grain daily for ten to twelve days in an average sized adult, but in the debilitated and those of low body weight smaller doses are advisable. Children receive a dose proportionate to age, those under three not exceeding $\frac{1}{8}$ th grain and those under six $\frac{1}{3}$ rd grain per day. The

drug has a cumulative action, and for this reason injections should not be repeated until an interval of three weeks has elapsed. Toxic symptoms include diarrhoea, asthenia, extreme muscular weakness and paresis of the limbs. At first emetine tends to slow the pulse, but where poisoning ensues tachycardia and cardiac irregularities may follow which sometimes prove fatal. The main indication for injecting emetine is hepatitis or amœbic abscess, the tissue-invading amœbæ in this situation being eradicated more effectively by the alkaloid than by any other known treatment. *Emetine-Bismuth-Iodide* (E.B.I.) is preferable in chronic cases and in carriers showing cysts. Owing to its tendency to cause nausea and vomiting, it should be given on an empty stomach late at night in gelatine capsules at least four hours after the last meal. A sedative like tincture of opium (15 to 20 minims) or luminal (1 grain) may be given with advantage quarter of an hour before the capsules are taken. The course consists of 3 grains administered at night over a period of ten to twelve days, during which a light, low residue diet is advisable. Patients under this treatment lose weight, develop bradycardia and show a fall in blood pressure of from 10 to 20 mm. mercury. Some authorities advocate *Emetine-Periodide* (E.P.I.) for the reason that it causes less vomiting; it is given in a dosage of 6 grains per day in gelatine capsules for a period of ten days.

Arsenicals. Certain of the synthetic arsenicals have been used with considerable benefit in amœbiasis and, besides being amœbicidal, have a tonic action on the body. *Stovarsol* is given in tablet form, 4 grains twice daily for seven to ten days, but toxic erythema and even exfoliative dermatitis may follow its use. *Carbarsone*, which is a pentavalent arsenical, is definitely superior to this drug and is a very effective amœbicide both for the vegetative forms in the intestine and their cysts. Its results, however, have proved disappointing in hepatitis or amœbic abscess. *Carbarsone* is administered in a dosage of 0.25 gramme after breakfast and after dinner at night for a period of ten days, and can be given with safety to ambulatory cases on a full diet. In these respects it possesses great advantages over the more toxic emetine preparations, and where patients cannot go to bed is superior to all other treatments. *Yatren* No. 105 is an iodine-oxy-quinolin-sulphonic acid preparation and can be given either *per os* or *per rectum*. The adult dose consists of $\frac{1}{2}$ to 1 gramme of the powder in gelatine capsules twice daily for ten days. When given as a retention enema the bowel is washed out in the morning with 1 pint of sodium bicarbonate solution, and an hour later 200 c.c. of a 2.5 per cent. solution of *Yatren* is run into the rectum from a tube and funnel. Most patients have little difficulty in retaining this solution for eight hours. *Anayodin* consists of *Yatren* and 22 per cent. sodium carbonate to increase its solubility. It is given in keratin-coated pills, 4 grains, the adult dose being four pills thrice daily after food for eight days. A very efficacious treatment in chronic cases consists of *Emetine-Bismuth-Iodide* at night, with retention enemas of *Yatren* in the morning, and this leads to cure in at least 90 per cent. of cases.

Amœbic Hepatitis and Liver Abscess. The geographical distribution of amœbic hepatitis and liver abscess coincides with that of amœbic dysentery, but owing to the long latent period which may intervene between acquiring the bowel infection and the development of hepatitis or liver abscess this is not always evident. Again, only about 80 per cent. of cases of liver abscess give a history of diarrhoea associated with the passage of blood and slime *per rectum*, while multiple examinations of the stools and of scrapings obtained during sigmoidoscopy may fail to demonstrate *E. histolytica* or its cysts.

Pathology. The first stage in infection of the liver consists of the so-called amœbic hepatitis, and here the *Entamœbæ* have been carried up *via* the portal vein and distributed through the liver as emboli derived from thrombosed vessels draining submucous ulcers in the large bowel. Local necrosis of tissue follows and fusion of adjacent foci gradually produces an abscess, the commonest site for

which is the superior surface of the liver, especially on the right side. About 80 per cent. of abscesses are found in the right half of the liver, 10 per cent. in the left half and the remaining 10 per cent. in both. This peculiar distribution appears to depend on streamline effects in the portal vein. Where a large destructive abscess involves one half of the liver a left-sided compensatory hypertrophy of the other follows. Amœbic abscess of the lung may result from direct spread of a liver abscess through the diaphragm, but much more frequently the pathological condition at the right base is found to consist of collapsed lung or areas of broncho-pneumonia produced as follows: Immobility of the diaphragm secondary to an adjacent hepatic abscess leads to defective ventilation, air absorption and pulmonary collapse; finally, secondary bacterial infection supervenes. Amœbic abscesses may reach a great size and contain as much as 2 to 6 pints of chocolate or anchovy sauce pus; of those that rupture over 50 per cent. do so into the lung or pleura and about 25 per cent. into the peritoneal cavity. Other adjacent structures such as the pericardium, stomach, intestine, vena cava or kidney may be involved, and occasionally the bile duct. The pus is bacteriologically sterile in 80 to 90 per cent. of cases. The organisms which have been isolated include streptococci, *B. coli*, *Staphylococcus aureus*, *B. pyocaneus* and anaerobes. Generally the walls of liver abscesses are composed of shaggy necrotic tissue, the fibrous tissue barrier not being nearly as well developed as in hydatid cysts; for this reason secondary infection is a more dramatic complication in amœbiasis. Microscopic section of the wall of the abscess reveals vegetative amœbæ only in the deeper zones and in the areas of hyperæmia surrounding the abscess; they are absent from the necrotic lining and this explains why amœbæ are not demonstrable in pus until two to five days after the abscess cavity has been drained or aspirated.

Symptoms. A history of amœbic dysentery or diarrhœa while resident in the tropics or subtropics is frequently obtained, but the incubation period is very uncertain, liver symptoms appearing in some cases within a few weeks of an acute attack of dysentery and in others being delayed as long as twenty years after the patient has left the tropics. Rogers (60) recognised two types of liver lesions: (1) so-called amœbic hepatitis which consists of miliary amœbic abscesses originating from emboli containing *E. histolytica* lodging in the terminal portal venules; (2) frank amœbic abscess—generally single, but sometimes multiple.

Amœbic Hepatitis. This condition commences insidiously, with irregular remittent fever and sweating, and these features may be the only obvious clinical manifestations for weeks. The liver is generally enlarged, but pain and tenderness are by no means invariable. There is a moderate leucocytosis with some increase in the neutrophile polymorphonuclear cells, and investigation of the fæces may reveal cysts of *E. histolytica*. Functional tests for liver efficiency are of little value, since the condition is not a true hepatitis, and healthy hepatic parenchyma intervenes between the miliary amœbic foci.

Amœbic Abscess. The preliminary symptoms are similar to those described for amœbic hepatitis, and as the abscess develops the liver enlarges and pain and tenderness increase. Should the abscess be located in the upper right half of the liver and impinge on the diaphragm it causes referred pain to the right shoulder and deficient air entry at the right base, with physical signs such as diminished vesicular murmur and crepitations associated with a dry cough (tussis hepatica). Later it may rupture through the diaphragm and produce a secondary pulmonary abscess. Left-lobe abscesses may simulate gastric conditions and most frequently are present in the epigastrium. Tenderness and rigidity of the left rectus are present, œdema of the abdominal wall may indicate pointing, and in some cases actual fluctuation is demonstrable. Rupture may occur into the base of the left lung, the stomach or the pericardium. Abscesses on the inferior aspect of the right half of the liver are associated with marked downward enlargement of that organ and tenderness and rigidity of the right

rectus and adjacent muscles. Pain may be referred to the appendical area or the abscess may bulge into the right loin space. A feeling of weight is often complained of when walking; the patient may hold his right arm and fore-arm to the side to splint his liver, and for the same reason he commonly sleeps on the right side. In large abscesses, especially of the right side, bulging enlargement may be obvious, and in doubtful cases the chest should be measured. The fever is generally irregular, at first being normal in the morning, followed by an evening rise with considerable sweating, while later intermittent fever with rigors may ensue. Other features include loss of weight, a sallow earthy colour of the skin, moderate anæmia, nervous irritability and not infrequently sleeplessness. X-ray examination is of value. In abscesses involving the superior surface it reveals immobility, elevation and sometimes bulging or pointing of the diaphragm and lesions at the right base. In central liver abscess there is sometimes, but by no means invariably, an area of increased density.

Laboratory investigations reveal a moderate leucocytosis of 15,000 to 25,000

FIG. 102.—Temperature chart in liver abscess. Note disappearance of pyrexia three days after injections of emetine commenced.

perc.mm. with polymorphonuclears from 75 to 90 per cent. Urobilinuria is common. Thick, chocolate or anchovy sauce pus containing degenerate polymorphonuclear leucocytes, cholesterin and hæmatoidin crystals is almost pathognomonic of amœbic abscess, while the stools may contain the cysts of *E. histolytica*; not infrequently, however, even multiple faecal examinations are negative.

Complications. The most fatal complications are secondary streptococcal infection or rupture into the lung, pleura, peritoneum or adjacent viscera. Pulmonary lesions, including collapse, broncho-pneumonia and pleural effusion, are not uncommon, especially where the abscess impinges on the diaphragm. Jaundice and hæmatemesis are rarely recorded, but they may both occur.

Diagnosis. Liver abscess may simulate a variety of conditions, including subphrenic abscess, perinephric abscess and suppurating hydatid, all of which may implicate the base of the right lung. Suppurating pyelophlebitis, cholecystitis, septic cholangitis especially complicating clonorchis infestation, bilharzial cirrhosis, gumma, primary carcinoma of the liver and malaria hepatitis may also cause difficulty. The history of diarrhoea and dysentery, the presence of cysts of *E. histolytica* in the stools, fever of hectic type associated with upward

enlargement of the liver and pulmonary features, the leucocytosis and the X-ray findings are important features. The aspiration of anchovy sauce pus from the abscess clinches the diagnosis, and short of this the dramatic drop of temperature within forty-eight to seventy-two hours of commencing emetine treatment favours its amœbic origin (see Fig. 102).

Prognosis. The prognosis depends on the type of treatment adopted, the presence of complications such as secondary bacterial infection or rupture into adjacent viscera, and on whether the abscess is multiple or single. Hepatitis responds specifically to emetine injections. Aspiration under sterile conditions combined with emetine injections (1 grain daily for ten days) has led to a great reduction in mortality, the figures varying from 1·6 per cent. to 14·4 per cent. Open operation with incision and drainage has a high mortality owing to secondary bacterial infection, especially if the transpleural approach be necessary.

Treatment. *Emetine:* Amœbic hepatitis and small abscesses of the liver are curable by emetine injections alone, 1 grain being given daily for ten to twelve days. A total course of 12 grains should not be exceeded even in patients of high body weight, while those under 8 stones should not receive more than 8 grains in one course; where necessary the injections may be repeated in two or three weeks' time. Even in the presence of large abscesses which need aspiration later the temperature falls to normal in about three days, and there is a more gradual fall in the leucocyte count. If there is any anæmia a reticulocytosis is observed from the seventh or eighth day. Pain and discomfort are generally decreased by emetine in hepatitis or small abscesses, but where the abscess is about to burst these symptoms may increase and then immediate aspiration is required.

Aspiration. Unless the site of the abscess is indicated by local features such as tenderness, œdema of the tissues, bulging, or by X-ray findings, the liver should be thoroughly explored by a needle of fair-sized calibre not exceeding $3\frac{1}{2}$ inches in length so as to avoid perforation of the vena cava. If an abscess on the upper aspect of the right lobe be suspected the needle or cannula should be inserted into the eighth or ninth interspaces on the right anterior axillary line and pushed inward, backward and slightly upward, aspiration being maintained by means of a large syringe attached to the needle or a Potain's aspirator. Failure to locate the abscess at the first attempt is frequent, and as many as eight punctures in different areas of the liver may be made before pus is obtained. Generally aspiration can be performed under local anæsthesia, but in certain cases a general anæsthetic may be preferred. As a rule one complete aspiration suffices, but sometimes the fever and leucocytosis persist or recur owing to the cavity having refilled, and then repeated aspirations may prove necessary.

In abscesses involving the inferior surface of the right lobe or in small left lobe abscesses exploratory puncture may be deemed inadvisable owing to the danger of causing peritonitis. Under these circumstances an exploratory incision should be made through the anterior abdominal wall and the abscess aspirated either with a Potain's aspirator or rubber tubing attached to a water pump. Subsequently the liver should be sutured and the wound closed without drainage, provided the pus be sterile.

Incision and Drainage. Practically the only indication for this operation is where secondary bacterial infection has occurred. Under these circumstances the cavity must be drained and continuous irrigation of the abscess cavity with Dakin's solution or eusol as advocated by Kilner (61) should be employed. Where an hepatic abscess ruptures into the lung the contents are generally coughed up through an hepatico-bronchial fistula and the condition generally clears up with emetine injections. After the liver abscess has healed the patient must undergo a course of treatment for his colonic infection, and for this purpose either emetine-bismuth-iodide or carbarsone are indicated. Emetine injections, though lethal to amœbæ in the liver or lung, frequently fail to eradicate bowel infection.

Ciliate dysentery is an ulcerative condition of the large intestine caused by *Balantidium coli*.

Ætiology. This ciliate has a widespread geographical distribution in different parts of Europe, Asia, Africa and America. Infections occur in people having occupational associations with pigs, which are the main source of infection. *Balantidium coli* is pear-shaped, measuring 50 to 80 microns in length and 30 to 55 microns in breadth. The peristome is situated at its anterior end, while internally there is a sausage-shaped macronucleus, a micronucleus and vacuoles. The exterior is covered by longitudinal rows of cilia over the whole surface. Encysted forms are found in the fæces and reproduction is by transverse fission.

Pathology. The ulcers, which are very similar to those in amœbic dysentery, have undermined edges. The ciliates are found in the ulcer base and surrounding tissues as well as in the lymph spaces, blood vessels and lymphatic glands in the infected area. The ciliates are found occasionally in the lower part of the small intestine, but rarely produce ulceration there.

Symptoms. Many cases are latent, patients having no bowel disturbances at all and the ciliates being found accidentally. Diarrhœa and definite dysentery with the passage of muco-sanguineous stools are found in other cases, and anæmia, inanition and digestive disturbances follow. Intestinal perforation or hæmorrhage may occur, but never abscess of the liver.

Diagnosis. Sigmoidoscopy reveals the presence of ulcers in the large bowel resembling those of *Entamœba histolytica*, and diagnosis will depend on the demonstration of the ciliates in scrapings from the ulcer bases or in the excreta. The *Balantidium coli* not infrequently disappears from the stools of infected individuals for considerable periods of time, but reappears later. During the latent intervals diagnosis is impossible.

Prognosis. If latent cases be taken into consideration the mortality is about 7 per cent., while in those showing colonic manifestations it is 29 per cent.

Treatment. A diet low in carbohydrate and high in protein and fresh vegetables has been advocated, and arsenical preparations like stovarsol in doses of 0.2 gramme twice daily after meals for one week, or carbarsone 0.25 gramme twice daily after food for ten days are worth a trial. High colonic irrigation with various solutions including quinine, silver nitrate and iodine have been recommended, while methylene-blue *per os* or given as an enema (1 in 3,000) can be tried. Owing to the spontaneous disappearance of the ciliates from time to time it is difficult to assess the value of different remedies.

Flagellate Diarrhœa. The human intestinal flagellates are *Giardia intestinalis* described by Lambl in 1859, *Trichomonas hominis* described by Lavaine in 1860, and *Chilomastix mesnili* discovered by Wenyon in 1910. Their pathogenicity is not universally accepted and no pathological evidence is forthcoming that they ever invade the intestinal mucosa. They appear to be more common in people suffering from diarrhœa than in normal individuals, but the encysted flagellates are often found in normal stools. Dobell has shown that the free flagellate forms are especially adapted to a fluid environment and for this reason they may only appear when the stools become liquid or loose. Of the three flagellates, *Giardia intestinalis* has the greatest claim to pathogenicity.

Giardiasis or Lambliasis. The normal habitat of *Giardia intestinalis* (*Lamblia intestinalis*, *Giardia Lamblia*) is the jejunum and duodenum, while occasionally it passes up the bile ducts or back into the stomach. A decrease or absence of hydrochloric acid predisposes to infection and after short-circuit operations such as gastro-jejunostomy, *Giardia* may appear in the gastric juice. They are pear-shaped flagellates varying from 10 to 18 microns in length and 5 to 10 microns in breadth and possess a concave sucker on the ventral surface of the body. The cysts are ovoid bodies from 8 to 14 microns in length and contain four small spherical nuclei, central axonemes and flagelli. No cytostome is present, fluid nourishment being absorbed through the surface of the body.

Pathology. As Wenyon points out, hyper-infection may lead to mechanical irritation of the surfaces of the small intestine, but there is no tendency to penetration of the epithelial surfaces or to ulceration.

Symptoms. The flagellate forms are only found in loose stools which may contain an excess of mucus, but never of blood. Whether the flagellates are responsible for the diarrhoea or the loose stools permit flagellates appearing in carriers containing encysted forms is controversial. Where no other pathogenic agent is present it appears rational to attempt to eradicate the infection. Cases, however, never die or become really seriously ill in the absence of an associated cause.

Treatment. Where achlorhydria exists hydrochloric acid therapy is indicated. No certain specific drug is available, but carbarsone, stovarsol and yatren appear sometimes to lead to the disappearance of both the flagellate and encysted forms. A diet high in protein and green vegetables and poor in carbohydrate is advised by Hegner. Lavage of the duodenum with concentrated magnesium sulphate solution (25 per cent.) may also prove useful.

Helminthic Diseases

There are three groups of helminths which may produce disease in man: (1) Trematodes or flukes infesting the intestine, liver, lungs or vascular system; (2) Cestodes or tape-worms which occur as adults in the intestine or as cysts in the tissues; (3) Nematodes or round-worms which may have either an intestinal or a somatic location. Pathogenic effects result from reflex disturbances, depressed gastro-intestinal function, anæmia of different types, direct mechanical action, the deposition of eggs and embryos in the tissues, secondary bacterial infection, toxic substances secreted by the parasites and helminthic anaphylaxis which is by no means an uncommon phenomenon.

DISEASES DUE TO TREMATODES OR FLUKES

The trematodes or flukes are parasitic non-ciliated worms with an unsegmented body which is generally flattened though sometimes more or less cylindrical. One or more suckers are present, the anterior one, known as the oral sucker, surrounding the mouth. In man their habitat may be the intestines, the bile ducts, the lung or the portal system and adjacent plexuses of veins.

Fascioliasis. Several flukes of the family *Fasciolidae* are known to infest man and other animals. The most frequent human species is *Fasciolopsis buski* (*Distoma crassum*), while that most commonly infesting animals is *Fasciola hepatica* (*Distoma hepaticum*). *Fasciola gigantica* has only once been recorded in a human being. Fascioliasis is a rare infection in man.

(1) *Fasciola hepatica* is commonly encountered in sheep, where it inhabits the bile ducts, causing liver rot; occasionally man is infected.

Ætiology. The eggs which are found in the fæces are operculated and oval in shape ($130-145 \times 70-90 \mu$) containing a miracidium. On escaping in water the miracidia infect snails of the species *Limnæa truncatula* and develop into sporocysts, rediæ and cercariæ in the liver. On escaping the cercariæ encyst on grass, etc.; the cyst wall is digested in the duodenum and the emerging meta cercariæ find their way to the bile ducts, after penetrating the gut wall and piercing the liver from the peritoneal surface.

Pathology. In animal infections the flukes mechanically obstruct the bile ducts, producing cystic dilatation and jaundice. Their toxins induce hypertrophy of the lining epithelium and a biliary type of cirrhosis with or without ascites. Generalised toxæmia associated with eosinophilia may result. Secondary infection may lead to infective cholangitis and liver abscess. Occasionally *F. hepatica* involves the blood vessels, lungs, ocular and subcutaneous tissues and even the brain.

Symptoms. If the infection be a light one there are no symptoms. In severe cases an enlarged tender liver, dyspepsia and other symptoms develop and death may finally result from infective cholangitis or liver abscess.

Diagnosis is established by demonstrating the operculated eggs in the faeces. In Syria in the Lebanon it is customary in connection with certain religious ceremonies to eat the raw livers of sheep and goats and if these be infected with *F. hepatica* the flukes not infrequently attach themselves to the human pharynx where they may produce oedema and congestion involving adjacent structures such as the soft palate, larynx, and eustachian tubes. Difficulty in swallowing, deafness and dyspnoea may be induced and if oedema of the glottis develops death from asphyxia may ensue. The disease locally is called halzoun.

Prognosis. This is grave in severe hepatic infections unless appropriate treatment be adopted.

Prevention. Halzoun is readily prevented by refraining from eating raw infected livers, while care regarding boiling of water and not eating water-cress or raw vegetables in infected areas will prevent hepatic fascioliasis.

Treatment. There is little information regarding the specific drug treatment in human beings, but both carbon tetrachloride and flix-mas administered in a dosage appropriate to body weight and repeated in twenty-four hours are very effective in sheep. Treatment with calcium salts has been found advisable wherever calcium deficiency exists, as this procedure exerts a protective influence on the liver, preventing the development of the toxic necrosis which sometimes follows the administration of carbon tetrachloride.

(2) *Fasciolopsis buski* (*Distoma crassum*). This is a giant intestinal fluke which is found in China, Assam, Bengal, Malaya and Borneo.

Life Cycle. The immature ova escape in the faeces and after three to seven weeks the miracidium attains maturity; it escapes through the operculum and invades the liver of certain molluscs (*Planorbis canosus* and *Segmentina nitidula*, etc.) where it produces sporocysts, rediae and cercariae, which on escaping encyst on such water plants as water chestnut and water caltrop. It is by eating infected corns that man becomes infected, the cercariae encysting and maturing in the duodenum.

Pathology. At autopsy the flukes are found attached to the mucosa of the small intestine—particularly the duodenum and occasionally the stomach and large bowel. Localised inflammation, hæmorrhages and even abscesses may result.

Symptoms. In light infections the patient complains of epigastric pain and dyspepsia relieved by taking food. In severer cases these symptoms may be accentuated and later a dry harsh skin, oedema of the face and extremities, asthenia, emaciation, diarrhoea and ascites may develop.

Diagnosis. The disease may simulate enteric infection or gastric or duodenal ulcer, but the eosinophilia will suggest helminthic infestation, and examination of the faeces shows the operculated ova of *F. buski* ($120-130 \times 75-80 \mu$).

Prevention consists in sterilising night-soil and boiling water caltrops and water chestnuts before use as food.

Treatment. Carbon tetrachloride in a dosage of 3 c.c. followed by an aperient or two doses of beta-naphthol (2 c.c. each) are curative.

Paramphistomiasis. There are two species of the family *Paramphistomidae* which produce disease in man, namely *Gastrodiscoides hominis* and *Watsonius watsoni* (*Pseudodiscus watsoni*). *W. watsoni* is reddish-yellow in colour, inhabits the duodenum and jejunum and measures 8-10 mm. \times 4-5 mm.; its ova are $120-130 \mu$ long and $75-80 \mu$ broad. *Gastrodiscoides hominis* has a large posterior sucker by which it adheres to the mucosa of the colon: it is 5-8 mm. long and 3-4 mm. broad, its ova measuring $150 \times 72 \mu$. Symptoms consist of intestinal disturbances, including the passage of bilious stools and diarrhoea. Diagnosis is made by finding ova in the faeces. Carbon tetrachloride (3 c.c.) appears to be specific.

✓ **Clonorchiasis.** This disease is produced by the Chinese liver fluke, *Clonorchis sinensis*, which invades the bile ducts of man and other mammals, producing biliary cirrhosis (see Plate 68, 20).

✓ **Ætiology.** *Clonorchis sinensis* is a spatulate fluke (10-20 mm. × 2-5 mm.) having operculated, yellowish-brown ova (27-35 × 11-20 μ). The eggs are passed in the faeces and the contained miracidium escapes into water, penetrating the oesophagus of the snail vector and burrowing into the periesophageal space where sporocysts, rediae and cercariae are formed. On escaping the cercariae penetrate the scales and flesh of certain fresh-water fish of the family *Percidae*, *Gobiidae* and *Anabantidae*; man is infected by eating the raw or undercooked fish. The gastric juice digests the outer capsule; in the duodenum the adolescaria escape and ascend the common bile duct to the liver, the left lobe of which is especially involved owing to the straighter course of the left bile duct (Faust).

Pathology. There is first desquamation of the biliary epithelium and ingestion of blood by the flukes which mechanically block the biliary passages, causing biliary stasis. Proliferation of biliary epithelium, periportal hyperplasia around masses of dead eggs, thickening of the ducts and general toxæmia follow. In hyper-infections the pancreatic ducts may be involved while secondary bacterial infection may lead to cholangitis and local abscesses.

Symptoms. In mild infections the disease is sub-clinical, but in severer infections anorexia, epigastric pain, discomfort and fullness after meals, diarrhoea and wasting follow. Enlargement of the liver, jaundice, œdema and ascites may occur.

Diagnosis is made by demonstrating the operculated ova in the stools.

Prognosis. Severely infected cases occasionally die from sepsis or other intercurrent disease, but the moderate and milder infections recover.

Prevention. This consists in adequately cooking fresh-water fish before its consumption, or in the destruction of the snail vector, which is much more difficult of achievement.

Treatment. Tartar emetic, if given intravenously, definitely reduces the intensity of infection, and Faust advocates gentian violet in the early cases as it invariably reduces the egg-cell counts. Gentian violet may be given as intravenous injections of an 0.5 to 1.0 per cent. solution on alternate days in quantities of 40 c.c.; a total course not exceeding 6 grammes or 100 grains is advisable. Alternatively, it may be administered orally in keratin-coated pills in a dosage of 2½ grains thrice daily after meals for ten days (Faust).

✓ **Paragonimiasis.** This is a disease caused by the Japanese lung fluke, *Paragonimus westermanii*, which invades the pulmonary tissues and gives rise to cough and blood-stained sputum containing the operculated eggs of this parasite.

Ætiology. *Paragonimus westermanii* (*Distoma westermanii*; *D. ringeri*) is found in Japan, China, Formosa and Korea. The adults measure 7.5-12 mm. × 4-6 mm. and form cysts in the lung where the broad, oval, operculated eggs are deposited; they reach the exterior in the sputum, and occasionally in the faeces. Once the miracidium has become mature it emerges from its operculated shell and invades some species of *Melania* snail, notably *M. libertina*, where sporocysts, rediae and later cercariae are formed. The latter encyst in the gills, muscles and liver of certain fresh-water crabs or cray-fish such as *Potamon obtusipes*, etc. When raw or undercooked infected crab is eaten, the cyst wall is digested by the gastric juice and the adolescaria emerges in the duodenum, penetrates the small intestine, invades the abdominal cavity, perforates the diaphragm and pleura and so gains access to the bronchus where it encysts in inflammatory tissue and matures.

Pathology. Localised and generalised pulmonary fibrosis, cystic dilatation of the bronchi and tubercular-like abscesses are found. The cyst-like formation round the fluke generally communicates with the bronchus and by this means the eggs escape into the air passages. Similar cyst-like lesions may

occur in the intestinal mucosa, the pancreatic and bile ducts, the peritoneum, mesenteric glands, spleen, liver, pleura, muscles, testicles, orbit and brain.

Symptoms. Naturally the clinical picture varies with the distribution of the parasites, and a number of different types are described. (1) *Pulmonary type*. This is characterised by cough and hæmoptosis; there is rusty-brown or anchovy-sauce coloured sputum containing operculated eggs, while the physical signs are those of bronchial pneumonia, bronchiectasis or pleural effusion. (2) *Abdominal type*. Where the liver, spleen, pancreas or intestine are involved the clinical picture suggests disease of these organs. (3) *Cerebral type*. This may manifest itself by headache, insomnia, loss of memory, aphasia, ocular disfunction, Jacksonian epilepsy and paresis or paralysis of different types including hæmi-plegia and monoplegia.

Diagnosis. History of residence in an endemic area is important and hæmoptosis occurring in patients from the Far East should always lead to laboratory investigation for the operculated eggs of *P. westermani* in the sputum or faeces. Eosinophilia is common. The blood may yield a positive complement fixation reaction if tested against an antigen made from the adult flukes.

Prognosis. In severe infestations the prognosis is bad and cerebral cases are almost invariably fatal.

Treatment. Fresh-water crab and cray-fish coming from infected waters in endemic areas should not be eaten. Emetine and tartar emetic may temporarily relieve the pulmonary symptoms, but it is doubtful whether they really cure.

Schistosomiasis. Man is the definitive host of several species of blood flukes of the family *Schistosomidae* which inhabit the portal system and its tributaries and deposit their ova in certain of the hollow viscera such as the bladder (*Schistosoma hæmatobium*) and entero-colon (*Schistosoma mansoni* and *Schistosoma japonicum*). Occasionally man is infected with certain bovine species such as *S. bovis* and *S. matthei*, while in the Belgian Congo Fisher (62) has recently described a new species—*S. intercalatum*—which, like *S. hæmatobium*, possesses terminal-spined eggs, but whose habitat is the human intestine and not the bladder.

Life Cycle. When bilharzial eggs come in contact with water ciliated miracidæ escape, invade some suitable fresh-water mollusc, make their way to the liver and develop into sporocysts. These sporocysts in four to five weeks' time produce mature cercariæ, which on escaping into water have twenty-four to forty-eight hours in which to find a suitable host or to die. Though occasionally man may acquire the disease by drinking infected water, a much more common route is *viâ* the skin during bathing. The cercariæ invade the tissues through the sweat glands and proceed *viâ* the blood vessels to the portal system where they attain maturity in from six to seven weeks.

VESICAL SCHISTOSOMIASIS (Plate 68, 22-25, Plate 69.)

(Urinary Schistosomiasis Bilharziasis)

This is a chronic disease caused by *Schistosoma hæmatobium* characterised by vesical symptoms including terminal hæmaturia and terminal-spined eggs in the urine.

Ætiology. *S. hæmatobium* appears to have originated in the Nile Valley where it has existed for thousands of years, and actually Ruffer demonstrated the calcified eggs in the renal pelvis of a mummy of the 19th Dynasty. The adult worms were described by Bilharz in Cairo in 1851. The female is located in the gynæcophoric canal of the male worm which is simply a flat fluke with its edges enfolded like a curled leaf. The ova possess a sharp, terminal spine and measure 120-160 × 40-60 microns. The intermediary host is *Bulinus contortus* in Egypt, *Physopsis africana* in Natal and *Planorbis metidjensis* var. *tufouri* in Portugal. From the Nile Valley the disease has spread along caravan routes by invading armies and by the slave traffic to different parts of the world, including Africa, Madagascar, Cyprus, Portugal, Palestine, Persia and Arabia.

Pathology. Though the adult worms may be found in the mesenteric veins, their chief habitat is the vesical, prostate and uterine plexuses of veins which communicate *via* the inferior hæmorrhoidal plexus with the portal system. Ova are found in largest numbers in the bladder, prostate, seminal vesicles and urethra in the male and the cervix and vagina in the female. Since these plexuses drain into the inferior vena cava stray ova naturally filter out in the lung rather than in the liver, as is the case with the intestinal schistosomes. The various lesions which may be produced include bilharzial pseudo-tubercles, papillomata, ulcers, chronic fibrosis and thickening and contractures of the bladder wall. The lower third of the ureters is not infrequently involved, while ova may be deposited in the prostate, seminal vesicles and peri-urethral tissues. Bilharzia granulomata of the penis and vulva are sometimes encountered. Egg deposits in the lung may lead to mild degrees of pulmonary fibrosis. Lesions in the liver and intestine are less frequently associated with this species owing to the more scanty egg deposits in these situations; ova are not infrequent in the appendix.

Symptoms. In the early invasive stages fever, urticaria, eosinophilia, generalised body pains, headache, rigors and cough associated with splenomegaly and hepatomegaly may occur during the second and third months. Some three to twelve months may elapse before vesical symptoms appear and occasionally they may not be noted for several years. The early symptoms include burning urethral pain on micturition, frequency, urgency, perineal pain, aching of the loins and hæmaturia which is aggravated by exercise—especially horse-riding. The terminal hæmaturia occurs at the end of micturition and may be present more or less constantly or intermittently, lasting for a day or two. Sometimes intervals of many months intervene in which macroscopic blood is altogether absent from the urine. The blood is generally bright red, though occasionally dark worm-like clots may be passed; in the later stages it may be equally distributed throughout the whole specimen and here the source of bleeding is papilloma or carcinoma. Backache and loin pain are not uncommon and pain may also be referred to the perineum, along the urethra or to the supra-pubic region. Where the prostate is involved hemospermia may result and ova be demonstrated in the prostatic secretions at a time when they are absent from the urine. Occasionally dysenteric-like symptoms appear associated with the passage of terminal-spined eggs in the stools, and it is not uncommon to find them in fæcal mucus if searched for, even in the absence of intestinal symptoms.

Physical examination may reveal tenderness in the supra-pubic region, while on rectal examination there may be tenderness of the prostate and seminal vesicles.

Cystoscopy. The earliest indications of bilharzial infection are diffusely scattered, submucous tubercles which often involve the trigone and base of the bladder. Later papillomata, ulcers and "sandy patches" may appear, the latter being manifest by a bright yellow reflex caused by calcified ova. Involvement of the ureters, calculi and carcinoma may be revealed during cystoscopy.

X-ray Examination. Uroselectan injections may demonstrate polypi, calculi, dilated ureters or hydro-nephrosis, while radiograms of the lung may also show pulmonary fibrosis. **Urinary Examination.** At first the urine is acid in reaction, showing a deposit of blood and mucus. Microscopic investigation reveals pus cells, erythrocytes and terminal-spined ova which are specially concentrated in the last few cubic centimetres. Several examinations may be necessary before ova are demonstrable. With the onset of bacterial infection the urine becomes alkaline and copious deposits of pus occur. Renal insufficiency is indicated by lowering of specific gravity and a diminished capacity to excrete urea as indicated by the various tests of renal function (*q.v.*); nitrogenous retention develops. **Blood count.** A high grade eosinophile leucocytosis is encountered in the early invasive stages associated with urticaria and fever, the total leucocytes equalling 15,000 to 25,000 per c.mm., while the eosinophiles vary from 15 to 70 per cent. Later the total count and eosinophiles decrease and in chronic cases may become

normal. *Complement fixation reaction.* During the early invasive stages, before eggs appear in the urine, the serum gives a strongly positive reaction against an antigen prepared as an alcoholic extract of cercarial infested livers. This reaction persists in many cases throughout the whole course of the disease, but its intensity often decreases and the percentage of positive reactions is lower in the more chronic phases of schistosomiasis. The reaction is essentially of group nature and fails to differentiate the different species of schistosome infecting man. *Intradermal test.* This test reveals hyper-sensitiveness to bilharzia protein and is performed by injecting intradermally 0.25 c.c. of a 1 per cent. filtered saline extract of cercarially infested liver. Positive reactions are obtained in a large proportion of patients who have suffered from schistosomiasis, but no indication is afforded as to whether the infection is of immediate or remote origin.

Complications. Secondary bacterial infection may result in septic cystitis, ascending pyelonephritis and pyonephrosis, while bilharzial stricture or blockage

FIG. 103.—Case of vesical bilharziasis (*S. haematobium*) showing the disappearance of viable ova from the urine following tartar emetic treatment.

of the ureter by papillomata may result in back pressure leading to hydronephrosis or chronic interstitial nephritis. Penile carcinoma, urethral fistulae and peri-urethral abscess are not uncommon, while calculi and vesical carcinoma are late complications. Fergusson stressed the association of *S. haematobium* and vesical carcinoma, pointing out that it was the common cancer of Egypt. Bilharzial granulomata may involve the labia, vagina, cervix, uterus and Fallopian tubes in addition to the vesical lesions described above.

Diagnosis. Various investigations such as microscopic examination of urine for terminal-spined ova, cystoscopy and serological tests described will enable a diagnosis to be made.

Prognosis. In the early stages the prognosis is entirely satisfactory provided appropriate treatment be instituted. Renal insufficiency, secondary bacterial infection and the incidence of such complications as carcinoma naturally increase the gravity of the disease.

Prevention. The avoidance of contact with infected water, the elimination or destruction of the snail vector, the prevention of contamination of water supplies with excreta and the eradication of the disease by specific remedies constitute the measures destined to prevent this disease.

Treatment. Specific drugs are available, the most important being the trivalent antimony compounds—tartar emetic and foudadin. Emetine hydrochloride exerts a lethal action on the adult schistosomes, but owing to its toxic properties it is less satisfactory. (1) *Tartar emetic*. The treatment of schistosomiasis by tartar emetic was successfully introduced by Christopherson who gave the drug intravenously in 10 c.c. of saline every second day, commencing with $\frac{1}{2}$ grain doses and increasing each injection by $\frac{1}{2}$ grain until a maximum of 2 grains was given. A fresh solution must be prepared on the day on which the injection is administered, and sterilised by boiling. For an adult of average weight the total course should equal 30 grains. The action of the drug is to kill the schistosomes in the vascular system and following its use viable ova rapidly disappear from the excreta (Fig. 103). Owing to its tendency to cause vomiting the drug should be given on an empty stomach some four hours after a meal. Spasmodic cough often follows in half to one minute, and during the later stages muscular pains not infrequently follow its administration. In uncomplicated cases the drug is well tolerated, but patients with renal involvement, sepsis or hepatic cirrhosis are unsuitable. During intravenous injections the greatest possible care has to be taken not to inject the drug into subcutaneous tissues as otherwise severe inflammation and extensive necrosis and ulceration result. (2) *Foudadin or neo-antimosan*. It possesses the great advantage that it can be injected intramuscularly instead of intravenously, while toxic manifestations are rare. The injection should be given in an all-glass syringe, 6 per cent. solution being utilised. The total course consists of 40 c.c. given in a series of nine intramuscular injections covering a period of fifteen days. (3) *Emetine hydrochloride*. Tsykalas advocates emetine in a dosage of $1\frac{1}{2}$ grains daily for a period of ten days. Though effective it is a dangerous drug and now that foudadin is available for intramuscular use in both children and adults there is little reason for its administration. Various complications referred to in the text must be treated along medical and surgical lines as they arise.

INTESTINAL SCHISTOSOMIASIS

This is a chronic colitis caused by *Schistosoma mansoni* occurring in various parts of Africa and South America. The adult worms inhabit the branches of the portal veins in the liver and the mesenteric veins. Their eggs, which possess sharp lateral spines, measure $140-150 \times 60-70$ microns and are an elongated, oval shape. *Planorbis boissyi* is a common vector in Egypt, *Physopsis africana* in Natal and *Planorbis olivaceus* in South America and *P. quadeloupensis* in the West Indies, which were infected through negro slaves coming from West Africa.

Pathology. Egg cell deposits may in the early stages lead to congestion and excessive mucus production and later to tiny tubercles, small sessile masses or pedunculated growths which may attain an enormous size and on sloughing leave a circular ulcer in the colonic mucosa. The appendix is commonly implicated and bilharzia tubercles may involve the subserous coats and be mistaken for tuberculosis. In the later stages periportal hepatic cirrhosis is common and this may be associated with splenomegaly. Bilharzial myelitis of the spinal cord has been recorded.

Symptoms. Primary fever with urticaria, eosinophilia, bronchial features, abdominal pain, hepatomegaly, splenomegaly and diarrhoea may occur, while later lateral-spined eggs appear in the faeces. The pyrexia lasts from one to seven weeks and was not uncommonly seen in British troops in Egypt during the Great War. Bowel symptoms appear from about the third month after exposure to infection and may be so mild that little attention is paid to the condition. Generally there is a history of acute attacks of diarrhoea and the passage of blood and mucus in the stools associated with tenesmus. These attacks occur at intervals and are precipitated by chill and dietetic indiscretion.

In between attacks the stools are solid and often coated with mucus in which lateral-spined eggs are found, while in chronic cases bilharzial papillomata may form, producing soft masses palpable through the abdominal wall; they may cause considerable distress if present in the rectum and may protrude through the anus, causing prolapse. Bilharzial granulomata and fistulæ may implicate the buttocks and anus and occasionally epithelioma supervenes. Periportal cirrhosis and splenomegaly not infrequently complicate chronic cases and this parasite is one of the accepted causes of Egyptian splenomegaly.

Diagnosis. In addition to demonstrating ova in the fæces, sigmoidoscopy and the complement fixation reaction afford important information in diagnosing these bilharzial lesions from those of amœbic and ciliate dysentery and ulcerative colitis. Repeated stool examinations may be necessary to demonstrate ova in light infections. Sigmoidoscopy may reveal small hæmorrhages or whitish bilharzial pseudo-tubercles in the early stages and later papillomata and ulcers. Scrapings from these lesions obtained with a blunt curette generally contain demonstrable ova.

Prognosis. Except in advanced cases[✓] with cirrhosis or other severe complications modern therapy is effective.

Treatment. Prophylactic and curative treatments are similar to those already described for vesical schistosomiasis. Splenectomy may be necessary in cases of Egyptian splenomegaly due to *S. mansoni*.

ASIATIC SCHISTOSOMIASIS

(*Katayama Disease, Yangtze Valley Fever.*)

This disease is a chronic colitis encountered in the Far East, caused by *Schistosoma japonicum*. The worms inhabit the portal system, while their eggs are oval, measuring $70-100 \times 60-75$ microns and show a lateral knob. The intermediary hosts are operculated snails; in the Yangtze Valley *Oncomelania hupensis* is the vector and in the south-east coast of China and Japan *Oncomelania nosophora*. Cases have been recorded in the Philippines and Formosa.

Pathology. At autopsy colonic thickening with scarring and possibly papillomata involving the mucosa are found. The mesentery is thickened and shortened, and large, firm retroperitoneal glands may be found matted together resembling tumours. Other lesions consist of thrombosis of the portal and mesenteric veins, periportal cirrhosis of the liver and splenomegaly. Fibrosis of the lungs and granuloma of the brain are recorded.

Symptoms. Cercarial dermatitis may result from the invasion of the skin by cercariæ with any of these schistosomes, but it appears particularly common in the Asiatic type, reaching a maximum in one to one and a half days. The initial toxic stage is characterised by an irregular remittent fever which may last several weeks and is often associated with urticarial rashes, transient œdemas of the subcutaneous tissues, pain in the epigastrium and hypogastrium, vomiting, diarrhœa, dyspnœa and cough. Examination may show splenomegaly, hepatomegaly, moist sounds and dullness at the bases of the lungs and intense eosinophilia. In this stage the complement fixation reaction is strongly positive and dermal hyper-sensitivity may be demonstrated. The next stage sets in from the end of the third month onwards with tenesmus, and the passage of mucosanguineous stools containing lateral knobbed ova. The colon now becomes tender and palpable and digestive disturbances and signs of malnutrition appear. The third stage presents evidence of portal obstruction with ascites and hepatic insufficiency. Bilharzial granulomata of the brain present a picture suggestive of cerebral tumour including headache, vomiting, optic neuritis, various forms of nerve paralysis and epilepsy of Jacksonian type.

Diagnosis. During the toxic stage enteric fever, food poisoning and pulmonary tuberculosis may be suspected, but the eosinophilia and complement

fixation reaction should enable the bilharzial origin of the condition to be recognised even before ova appear. Dysenteric features associated with enlargement of the liver are common to both amœbiasis and intestinal schistosomiasis and diagnosis is only possible by sigmoidoscopy and laboratory procedures.

Prognosis. In patients subject to repeated reinfection death is not infrequent, but provided the liver is reasonably healthy and intercurrent disease is not present the response to modern therapy is satisfactory as a rule. It is, however, the most difficult of all human species to cure.

Treatment. Treatment is similar to that outlined for other species of schistosoma infestations. Cases with cerebral granulomata should receive an intensive course of tartar emetic treatment before decompression is attempted.

Heterophyidiæ. This disease is due to infection with flukes of the family *Heterophyidae*. Three species may infest man—*Heterophyes heterophyes*, *Heterophyes katsuradai* and *Metagonimus yokagawai*.

Heterophyes heterophyes (*Distoma heterophyes*, etc.): this minute fluke infests the intestine of man and other mammals like the dog and cat. It is exceedingly small, measuring only $1-1.7 \times 0.3-0.4$ mm. and deposits oval-shaped, light-brown operculated ova measuring $28-30 \times 15-17$ microns. Man becomes infected by eating mullet in which cercariæ have encysted. Infections with the other species are so rare that no detailed description is necessary.

At autopsy the flukes are found attached by their suckers to the intestinal mucosa where they induce mild inflammatory reactions and local eosinophilia. In milder infections the condition is sub-clinical, but where larger numbers of parasites are present intestinal disturbances result with indigestion, diarrhœa and malæna. Diagnosis is made by finding the operculated eggs of *H. heterophyes* in the stools. Regarding treatment, carbon tetrachloride, beta naphthol and thymol are all effective. Owing to the small size of the flukes the stools must be strained through fine mesh muslin as they are liable to be lost on ordinary sieving.

DISEASES DUE TO CESTODES OR TAPE-WORMS

Adult cestodes are elongated, ribbon-like structures divided transversely into segments known as proglottides, while at the narrow anterior end is the *scolex* which is joined to the segmented portion by a narrow neck. Adult tape-worms produce intestinal teniasis in man and other animals acting as definitive hosts. Somatic teniasis results where the developmental stage is passed in the muscles or tissues of the intermediary host.

Intestinal Cestodiasis. (1) *Tænia solium*: the pork tape-worm is encountered in the upper third of the small intestine of man. It measures from 6 to 10 feet in length, possesses a globular head, four suckers, a *postellum* and two circular rows of hooks which alternate with each other. The uterus lies in the long median plane of the proglottis, is tubular in shape and possesses not more than twelve branched lateral diverticula. Its ova are spherical in shape, measure 30 to 40 microns in diameter, have a thick walled shell and contain an oncosphere with three pairs of hooklets. The gravid proglottides become detached and are evacuated in the fæces where they disintegrate and liberate the eggs. These are taken into the alimentary tract of the intermediary host, the pig, either in contaminated water or when the animal is grubbing for food. Man himself sometimes becomes the intermediary host. On ingestion the shell is dissolved and the oncosphere is liberated in the stomach; subsequently it passes through the gut wall, enters the circulation and is deposited in the connective tissues of the muscles, where a capsule is formed around it as a result of tissue irritation. Here it develops into a bladder-like structure known as *cysticercus cellulosæ* which varies in size from $5-20 \times 5-10$ mm. When these cysticerci are eaten by the definitive host the bladder is digested and the scolex liberated. In the upper

part of the small intestine the scolex fixes itself to the gut wall and the neck proceeds to bud proglottides. The cysticercus stage is normally found in the muscles of the pig and human infections are acquired by eating "measly" pork which has been insufficiently cooked. The processes of pickling and smoking fail to kill cysticerci (see Plate 68, 28-30, p. 1066).

(2) *Tænia saginata*: the beef tape-worm is only found in the intestinal tract of man. It measures 9 to 12 feet, but occasionally is double this length. The scolex is pear-shaped or cubical, possessing four lateral suckers, no rostellum and no hooks. The uterus is tubular, median in position and possesses fifteen or more branched lateral diverticula, a feature which differentiates it from the proglottis of *Tænia solium*. Its eggs are indistinguishable from those of *Tænia solium*. The cysticercus stage is found in the ox (*Cysticercus bovis*) and man becomes infected by eating underdone beef. The cysterci die when cooked in water at a temperature of 48° C. (see Plate 68, 26 and 27).

(3) *Dipylidium caninum*: this tape-worm is normally a parasite of the intestine of dogs and cats, but is sometimes found in young children. Its length varies from 10 to 40 cm. and its breadth from 1.5 to 3 mm. It does not appear to be pathogenic.

Other rare human infections include *Bertiella satyri*.

(4) *Diphyllobothrium latum* (*Dibothriocephalus latus*): the broad, fish tape-worm varies in length from 6 to 30 feet, is greyish in colour and inhabits the small intestine of the dog, cat, fox and man. Its head is almond-shaped and possesses no armature. The eggs are operculated, elliptical in shape and measure 70 × 45 microns. Within three to five weeks the fertilised egg is transformed into a hexacanth embryo which escapes into water and after being ingested by cyclops it develops in the cœlomic cavity into a procercoid larva. If the infected crustacean is now swallowed by plankton-feeding fresh-water fish, such as pike, perch, salmon and trout, the larva develops in the muscles of the fish into the plerocercoid stage and man becomes infected by eating its flesh, provided it be insufficiently cooked.

Symptoms. Often no symptoms are produced, but in other patients dyspepsia, loss of appetite, colicky abdominal pain and diarrhoea ensue, while headache, convulsions and strabismus may be encountered in children. Infestations with *D. latum* are occasionally associated with severe megalocytic anæmia which responds specifically to liver extract treatment, but is only permanently cured if the tape-worms be eliminated by proper treatment.

Diagnosis. Diagnosis is based on the identification of the parasite by the demonstration of its segments or ova in the fæces. Eosinophilia may suggest helminthic disease. Skin hyper-sensitiveness to tape-worm protein may be demonstrated by the intradermal test.

Treatment. Filix-mas cures most patients provided there is preliminary dietetic treatment and adequate purgation with salines follow. For the two previous days the bowels should be opened with aperients and a liquid diet taken. Extractum filicis liquidum should be given in gelatine capsules containing 30 minims of the drug at 8.0, 8.20 and 8.40 a.m., while in cases which have previously been unsuccessfully treated an additional 30 minims may be given at 9 a.m. combined with 30 minims of oil of turpentine. Two hours later sodium sulphate ($\frac{1}{2}$ ounce) is administered. All motions for forty-eight hours after treatment should be collected, sieved and examined against a black background to identify the head of the worm. It takes about three months for segments to reappear where the worm has survived. An alternative treatment is carbon tetrachloride, which is given in capsules in a dosage of 3 c.c. for adults. This is followed by a saline purge three hours later. If there is any suggestion of calcium deficiency, calcium lactate, 30 grains thrice daily should be given for several days prior to the administration of this drug. Anæmia, if associated with intestinal tæniasis, should be treated with full doses of iron in the case of *Tænia saginata*.

and *Tænia solium*, and with liver extract in megalocytic anæmia associated with *Diphyllobothrium latum* infestation. Where gastric secretion is depressed, acid hydrochlor. dil. B.P. in a dosage of 1 drachm thrice daily after meals in diluted orange juice, is advisable.

Somatic Cestodiasis. After cestode eggs or proglottides are swallowed by the intermediary host, the embryonal shell is digested and the embryo set free: it attaches itself by means of its hooks to the intestinal wall, burrowing its way into the blood vessels and so to the internal organs or tissues for which it has a predilection. As a result of tissue irritation a limiting capsule forms around it and within this the larva develops. A number of different types are found, known as (a) a plerocercoid when it becomes tape-like with an invaginated scolex, (b) a cysticercoid when only slight bladder formation ensues and (c) cysts in which the bladder is well developed. Three varieties of these cysts are found: (1) a cysticercus proper in which there is one bladder and one scolex; (2) a coenurus in which there is one bladder cavity and numerous scolices; (3) an echinococcus in which these scolices develop in brood-capsules; daughter cysts may also be formed.

(1) *Sparganum mansoni*. This is the plerocercoid stage of *Diphyllobothrium mansoni* and has a life history resembling *D. latum*—the broad fish tape-worm. The habitat of the adult worms is the intestine of the dog and cat, and the ciliated embryo after escaping by the fæces must be ingested by a cyclops, *C. leucarti*, in which it develops into a proceroid larva. If this be now swallowed by a suitable ophidian, avian or mammalian host, including man, the cyclops is digested and the freed larva penetrates the stomach wall, travels subperitoneally to the somatic muscles, including those of the iliac and lumbar region, pleura, urethra and eye, where it undergoes an asexual multiplication by transverse fission. Many spargana are thus produced from a single plerocercoid. Should this infested tissue be eaten by the dog or cat the mature tape-worm, *Diphyllobothrium mansoni*, develops. The adult stage has never been observed in man.

Symptoms. Ocular sparganosis is common in the Tonkin Delta, and inflammation with pain, redness, injection of vessels, œdema, lacrymation and ptosis may result. Chinamen often acquire ocular infection through the practice of applying spargana-infected frogs for the treatment of ulcers. Myositis with pain, swelling and œdema of the adjacent subcutaneous tissues may ensue when the somatic muscles are involved.

Diagnosis. This is dependent on demonstrating the unbranched sparganum larvæ embedded in a slimy matrix in the tissues.

Treatment. Surgical removal of the larvæ is performed whenever feasible.

(2) *Sparganum proliferum*. This species of Sparganum affects man in Japan, but the adult stage and the life cycle are both unknown (Faust). Clinically, large numbers of spargana invade the tissues, producing extensive nodules and honeycombing, and where the lymphatics are implicated elephantiasis is said to result.

Cysticercosis. This is the cystic stage of *Tænia solium* which may involve the somatic muscles, the heart and its valves, the brain and its ventricles, the liver, lungs, orbital tissues and eye. Cysticercosis occurs in Europe, especially Germany, and is encountered in Africa, Madagascar and in soldiers returning from India and Egypt. Man probably acquires the disease by auto-infection or eating uncooked food contaminated with segments or ova of *T. solium*.

Pathology. The cyst, which may or may not be surrounded by a fibrous tissue capsule, consists of an opalescent bladder containing a single invaginated head with hooklets. In the eye, ventricles and pia mater cysts show little tendency to be encapsulated. Their size depends on their situation and age. In the brain they tend to be round and in the muscles to be oval in shape, attaining a length of 20 mm. when mature. Brumpt (63) points out that if the cyst dies or undergoes calcareous degeneration there is an intense local leucocytosis and

even suppuration may result. MacArthur (64) holds that death of the larvæ is associated with an increase in the quantity of fluid and that they then act as foreign irritants and often produce symptoms for the first time partly by mechanical means as a result of their swelling and partly from toxic effects. Calcification may occur in the scolex before it involves either the capsule or the cyst. Hypertrophy of the heart muscle and valvular trouble due to calcified cysticerci are described by French workers.

Symptoms.—The incubation period is difficult to establish since the majority of cases are not cognisant of having harboured the adult *T. solium*. Probably, it varies from a few months to several years in different cases. Prodromal symptoms are not common, but in certain cases during the invasive stage a history of fever, headache, myalgia and swelling of muscles subsequently found to be affected may be forthcoming.

(1) *Muscular Type*. The clinical manifestations are determined by the distribution and death of parasites. Palpable cysts may be detected in the subcutaneous tissues and muscles of any part of the body including the head, face, eyelids, tongue, lips, trunk and limbs. On palpation the size is generally that of a small pea, but occasionally they may appear as large as a pigeon's egg (MacArthur). Latency is a characteristic feature and cysts may suddenly appear or disappear in the most evanescent fashion. Muscular pains, tenderness and cramps may be complained of.

(2) *Nervous Type*. Epilepsy is by far the commonest manifestation. One out of every five soldiers returning from India with so-called idiopathic epilepsy does so on account of cysticercosis. The attacks may be Jacksonian in type, with or without loss of consciousness, or like those of petit mal. Aura, biting the tongue, sphincter incompetence and post-epileptic stupor may be present. Sometimes fits occur when subcutaneous cysts are first detected, at other times several years may elapse before epilepsy supervenes. Other cases present focal lesions of different types and cerebral tumour, disseminated sclerosis, encephalitis, and various psychoses associated with mental dullness, defective memory, disorientation, melancholia, acute mania and even delusional insanity may be simulated. Periods of exacerbation are often followed by intervals of quietude, so that at different periods the one patient may be regarded as suffering from delusional insanity, disseminated sclerosis and cerebral tumour.

(3) *Ocular Type*. Distension of the eye itself, exophthalmos, conjunctivitis, iritis, opacities in the vitreous, choroiditis or detachment of the retina may be produced. Cysts may be lodged either in the anterior or posterior chamber.

Naturally these types are not clear cut, but depend on predominant regional distribution of cysticerci. Other organs like the heart and liver are occasionally involved.

Diagnosis. Muscle and subcutaneous cysts may be mistaken for lipomata, von Recklinghausen's disease, secondary malignant deposits and nodular leprosy. The history of fits in a person who has resided abroad and has a clean family history and no head injury, syphilis or neoplasm is suggestive, while the cysts if palpable should arouse suspicion. Biopsy under local anaesthesia is always advisable; after incision of the cyst capsule a translucent membrane possessing a "milk spot" caused by the invaginated scolex is found. X-ray examination of the root of the neck, upper arms, fore-arms, thighs and legs may reveal calcified scolices or fully developed elliptical cysts (about 2.3 cm long), but seldom of the skull. Eosinophilia is rarely present and immunological tests such as the complement fixation reaction and the intradermal skin test, though sometimes useful, are frequently disappointing as negative results may occur in quite heavy infestations. Both tests are group reactions to *Tænia* protein and fail to differentiate the various species of *Tænia* infecting man. (Plate 70.)

Prognosis. According to MacArthur the most dangerous time is the sixth to the eighth year, as this is when grave intensification of existing cerebral

disturbances most frequently takes place and patients who have previously been free from cerebral features develop them. The general tendency once the cerebrum is involved is one of mental deterioration, but sometimes even those who have developed fits may recover completely. In consequence the prognosis is always difficult.

Prevention. Individuals infested with *T. solium* should be treated effectively without delay, and under-done pork should be avoided. Rigid inspection of pork at abattoirs by competent inspectors should be instituted.

Treatment. Surgical intervention is not of value and all that can be done is to control fits by means of luminal and bromide.

نقش قلمو

ECHINOCOCCOSIS (Plate 68, 35-37, p. 1066)

نقش قلمو (Hydatid Disease)

Hydatid disease in both man and domestic animals is the cystic or larval stage of the dog tape-worm, *Echinococcus granulosus*.

Ætiology. Infection is acquired by handling and fondling infected dogs or eating uncooked food or water contaminated with their fæces. Though hydatid disease has been recorded in all countries it is specially common where the sheep-raising industry flourishes as in Australia, New Zealand, Argentine, South Africa, Iceland, Bulgaria, Roumania and Algiers. In certain parts of Europe, like Greece, it is not uncommon. Indigenous cases occur in the British Isles.

Echinococcus granulosus (*Tænia echinococcus*) is a minute tape-worm measuring 3 to 6 mm. in length which inhabits the small intestine of dogs, jackals, wolves and occasionally domestic cats. The head is small, measuring 0.3 to 0.5 mm. in diameter and possesses a rostellum, a double row of rose-thorn hooklets and four suckers. The fourth or terminal segment is larger than the others and contains the sexual organs and eggs. The eggs, which measure 30×36 microns, resemble those of the other cestodes and contain a six-hooked embryo. As the terminal proglottides mature, they become detached and are passed in the fæces, so that a dog may excrete hundreds or even thousands of eggs daily. These eggs, either singly or in masses, may be swallowed in contaminated food or water by the intermediate host and on reaching the stomach and duodenum the shell is digested and the hexacanth embryo escapes, boring its way through the intestinal wall into one of the mesenteric vessels. Generally it is filtered out in the capillaries of the liver which it may reach in eight hours; less frequently it localises in the lung capillaries and elsewhere. The young embryo now loses its hooklets, becomes vacuolated and transformed into an hydatid follicle; many months later an elastic cyst is produced containing clear, limpid fluid surrounded by a lining membrane and adventitia. The cyst membrane consists of (1) an endogenous or germinal cellular layer which secretes hydatid fluid and buds little cysts containing scolices known as brood-capsules; (2) an outer laminated or exogenous layer composed largely of hyalin, the function of which is essentially protective; it is laid down by the endogenous layer. In addition, local host reaction produces a fibrous tissue barrier known as the adventitia which walls off the cyst from the surrounding tissues. On incision the cyst membrane is readily separated from the adventitia. As well as the fluid and brood capsules the original mother cyst may give rise to daughter and grand-daughter cysts containing scolices; the latter are really the embryonic heads of future tape-worms and are capable of retraction or evagination (Plate 68, 35, p. 1066) under a suitable stimulus. Sometimes the endogenous layer of the mother cyst fails to breed brood-capsules and daughter cysts and it is then known as a sterile cyst. At other times exogenous budding occurs; this is particularly common in bone and occasionally it is encountered in the liver where it forms a hard, globular, multilocular mass containing numerous alveoli containing cyst membrane and a jelly-like matrix. Alveolar hydatid of this nature in man has been

attributed to a separate parasite, *Echinococcus alveolaris*, but the existence of second species is improbable.

Distribution of Cysts. Hydatid cysts have been recorded in practically every organ and tissue of the body, but about 70 per cent. of primary cysts occur in the liver. Next in frequency in adults are the lung, muscles and subcutaneous tissues, kidney, spleen, bones, orbit and brain (Dévé) (65). In children brain hydatid is about seven times more frequent than in the adult, whereas bony hydatid is rare. Cysts are almost as frequently multiple as single; in the former event the liver is almost invariably implicated and two to six cysts are the rule, but as many as forty to sixty primary cysts have been recorded.

Changes in the Cyst. The local pressure effects depend on the site of the cyst, its rate of growth and the compensatory changes which take place in the implicated viscera. Sooner or later, however, some complication such as rupture, entry of bile, suppuration or death and degeneration of the cyst occurs. As age advances the adventitia becomes denser and less vascular and defective nutrition may result in non-secretion of fluid, collapse of the cyst and caseous degeneration of parasitic tissue with the production of putty-like *débris* in which convoluted layers of laminated membrane may still be recognised after many years. Infiltration with calcium salts, first of the adventitia and later of the whole cyst, may follow.

Symptoms. The incubation period varies with the rate of growth of the cyst which is slow in bone and rapid in the brain and lungs. From five to thirty years may elapse before symptoms are produced, and autopsy records show that the condition is subclinical throughout life in at least 30 per cent. of cases. Not infrequently it is the presence of some accident such as rupture or suppuration which draws attention to the presence of the cyst for the first time.

Diagnosis. (1) *Hydatid material.* Hydatid fluid may be aspirated during exploratory cyst puncture or pieces of membrane resembling grape skins may be coughed up or passed in the fæces or urine. Hydatid elements like scolices and hooklets may also be identified. Laminated membrane has a characteristic appearance, its curled edges resembling the leaves of a book. The fluid itself is clear like water or faintly opalescent, having a specific gravity of 1,008 to 1,015, and containing from 0.12 to 0.15 per cent. of coagulable protein as well as considerable amounts of sodium chloride (0.55 to 0.65 per cent.). Centrifugalisation generally reveals hooklets or scolices (Plate 68, 36 and 37). When the head is evaginated the scolex measures nearly 3 mm. in length and, in addition to its four suckers and double row of hooklets, the cytoplasm contains characteristic calcarious bodies. (2) *Leucocyte count.* A local accumulation of eosinophiles and a general eosinophilia accompany the early invasive stages, but the blood count may have returned to normal long before clinical symptoms are produced. Prior to operation only about one-third of patients with echinococcus are found to have an eosinophilia. Rupture of a cyst is followed by a definite eosinophilia and a post-operative rise occurs whenever fluid has been absorbed. Suppuration secondary to coccal infection leads to a neutrophil leucocytosis with decrease in the eosinophile elements. (3) *Precipitin test.* This is best performed by mixing 0.4 c.c. of carbolised sheep hydatid fluid (0.5 per cent.) with 0.4 c.c. of fresh clear serum (66). Final readings are made after thirty-six hours at room temperature, a positive reaction being indicated by the formation of a fine flocculent precipitate which slowly sinks to the bottom of the tube. The test is positive in some 65 to 80 per cent. of cases. (4) *The Complement fixation reaction.* Either hydatid fluid or an alcoholic extract of scolices may be utilised as antigen, sheep cysts being most suited for the purpose (67). Positive reactions are obtained in about 80 per cent. of patients before operation, but if those who have been formerly operated on be excluded the number does not exceed 60 per cent. Rupture or suppuration lead to absorption of antigen and 95 to 100 per cent. of sera are positive after these complications. Negative results are obtained in

degenerated or old cysts with a greatly fibrosed adventitia, also in sterile cysts, the fluid of which is poorly antigenic. A post-operative rise in complement fixation antibody is generally demonstrable, and this circulating body only slowly disappears. At least two years must elapse before any prognostic significance can be attached to a persisting positive reaction. (5) *Intradermal test* (Casoni reaction). This consists in the injection into the dermis of 0.25 c.c. of hydatid fluid filtered to ensure its sterilisation. Two types of reaction are encountered: (1) an immediate white wheal rapidly increasing to a diameter of 2.4 cm. or more with irregular peripheral out-runners and surrounded by a zone of erythema; (2) a delayed reaction characterised by a large area of erythema with a defined margin and swelling of the deeper subcutaneous tissues due to œdema coming on some six to twenty-four hours after the injection. The skin is tightly stretched, but not actually painful, though in hypersensitive individuals considerable discomfort and itching associated with great swelling, redness and even local vesiculation may ensue. Some 98 per cent. of active hydatid cases react positively so that a negative reaction in a suspected case is strong presumptive evidence against echinococcosis provided the injected fluid be antigenic. A positive reaction, on the other hand, by no means proves the presence of an hydatid cyst since the reaction is of group nature and cases of both intestinal tæniasis and cysticercosis in man may react positively as well as individuals sensitive to the protein of the host from which the fluid was obtained. Furthermore, as dermal sensitivity persists for many years after the complete surgical removal of all cysts, it follows that a positive skin test has no essential relationship to existing infestation.

Hydatid Anaphylaxis. Anaphylaxis, embolic phenomena and secondary echinococcosis may follow puncture or rupture of a cyst and the escape of hydatid elements into blood vessels or the serous sacs. Anaphylactic manifestations include sudden onset of urticaria, œdema, erythema and pruritis with or without chemosis, injection of the conjunctivæ, pallor, cold extremities, tachycardia, low blood pressure, syncope, tightness of the chest, asthmatic cough, cyanosis, dyspnoea, nausea, vomiting, diarrhoea, passage of blood *per rectum*, extreme nervousness, delirium, convulsion and coma. There is a concomitant eosinophilia, and death may occur rapidly from cardiovascular shock associated with intense bronchial spasm with or without pulmonary œdema or œdema of the glottis.

Sensitisation probably develops during the invasive stage before the formation of the laminated layer, and it is the escape of fluid following puncture or rupture many years later which precipitates the anaphylactoid reaction. Dermal sensitiveness to hydatid protein is always demonstrable in such cases and passive hypersensitiveness can be transferred by serum injections into either animals or man. Rarely the syndrome may be accidentally reproduced in its entirety when injecting hydatid fluid during skin testing in hypersensitive subjects. For this reason it is advisable to keep such patients under observation for at least an hour and to inject adrenalin (10 minims of 1/1,000 solution) immediately symptoms appears.

Hydatid of the Liver. About 75 per cent. of all hydatid cysts affecting man are situated in the liver and of these four out of every five occur in the right half of that organ. In contradistinction to amœbic abscess they tend to present at the inferior surface. *Simple or univesicular cysts.* These cysts which contain brood capsules and scolices, but no daughter cysts, occur specially in children and young adults. As a rule a tumour in the right hypochondrium or epigastrium is the first thing noted. If the anterior and inferior surface be implicated it presents as a rounded, cystic, non-tender swelling continuous with liver dullness which may attain enormous dimensions. Considerable deformity of the chest wall may result in children, due to widening of the intercostal spaces and bulging of the costal margin. As a rule pain is absent and the general health satisfactory.

According to Dew (68) rupture is rare under the age of fifteen years. *Multivesicular cysts*. Cysts containing daughters are much more characteristic of adult life and frequently the condition is only recognised when a large tumour has developed or complications have supervened. There may be discomfort, a feeling of weight or actual pain in the hypogastrium. If colicky in nature pain suggests the passage of cyst contents down the biliary passages and is often mistaken for gall-stone/colic. Gastric disturbances are common and include a sense of distension after meals, nausea, heart-burn and even vomiting. Dyspnoea and cough only develop where the diaphragm is encroached upon. Jaundice may be transient or persistent and in the latter case rupture into a bile duct or suppuration has supervened. Ascites is rare.

Physical examination in about three out of four cases reveals a rounded, cystic tumour continuous with liver dullness due to a cyst located on the inferior aspect of the liver; it is not tender and is freely movable with respiration. Hydatid fremitus or hydatid thrill, if present, is pathognomonic. Where the cysts develop downward below the stomach and colon a renal tumour may be simulated. Pulmonary signs at the right base are infrequent unless the cyst implicates the upper aspect of the liver (25 per cent. of cases) and impinges on the diaphragm. X-ray examination is necessary here to differentiate subphrenic from pulmonary cysts; immobilisation, distortion and elevation of the diaphragm may result. Cysts involving the upper aspect of the left half of the liver cause cardiac displacement and tend to present in the epigastrium in front of the colon and stomach; palpable enlargement in this vicinity, however, is much more often due to left compensatory hypertrophy associated with a large destructive cyst of the right half of that organ.

Complications. These include suppuration and rupture into a bile duct, the peritoneal cavity, the thorax, the alimentary tract or elsewhere.

(1) *Suppuration*. About 90 per cent. of suppurating cysts are multivesicular. The pus is always bile-stained, generally foetid in odour and may be associated with a variety of organisms including *Bact. coli*, staphylococci, streptococci, *Bact. proteus*, *Vibrio septique* and *Bact. aerogenes capsulatus* (68). Generally there is a history of previous dyspepsia, abdominal discomfort, pain or jaundice, but in some cases the onset is quite sudden, the earliest symptom being hepatic pain, often colicky in nature. Constitutional symptoms are, as a rule, less marked than would be expected and depend on the thickness of the adventitia and the virulence of the invading organism. The temperature is by no means constant, but intermittent fever with evening rises is common. In addition, rigors, sweats, anorexia, vomiting and diarrhoea develop, weakness increases, the skin becomes pale or jaundiced and later dyspnoea, wasting and cachexia result. Anaerobic infections are rapidly progressive with grave constitutional features.

Physical examination may reveal a tender tumour continuous with liver dullness, but with limited mobility owing to adhesions; the rectus is often rigid and respiratory movement limited. An effusion at the right base is frequently associated with subdiaphragmatic suppurating cysts, or signs of dry pleurisy, pulmonary congestion or broncho-pneumonia may be present in this situation. A neutrophil leucocytosis results with decrease in eosinophile cells. Suppurating hydatid may be confused with subphrenic abscess, amœbic liver abscess, cholecystitis, cholangitis, pyelephlebitis, basal pneumonia, perinephric abscess or an acute abdominal crisis such as a perforated duodenal ulcer. The history, the presence of a rounded tumour, immunological tests and X-ray examination will assist in their differentiation.

(2) *Intra-Peritoneal Rupture*. This is accompanied by peritoneal shock. There is sudden upper abdominal pain, vomiting, collapse and tachycardia. Anaphylactic symptoms, including urticaria and pruritis, may be superadded. Later still, where bile has leaked into the peritoneal cavity, the abdomen suddenly

enlarges and free fluid is demonstrable (choleperitoneum). Peritonitis follows if the original cyst was infected, while secondary peritoneal echinococcosis results years later with multiple cysts scattered throughout the peritoneum due to the implantation of daughter cysts, brood capsules and scolices.

(3) *Intra-Thoracic Rupture.* The tendency of cysts situated on the superior surface of the liver is to work upwards, elevating the diaphragm, compressing the lung or producing a passive pleural effusion; in some cases rupture through the weakened diaphragm into the adjacent lung tissue may follow, while in others it occurs into the pleural cavity or a bronchus. Generally suppuration precedes rupture. Hepato-bronchial cysts with or without empyema may result, in which case the sudden expectoration of bile-stained pus containing hydatid membrane or other elements will enable a diagnosis to be made. Natural cure may follow, but the presence of daughter cysts and the difficulty of draining a hepatico-bronchial cyst through a small bronchus militate against this, and prolonged suppuration, hæmoptysis, abscess formation or gangrene usually necessitate surgical interference.

Treatment. This is essentially surgical unless the cyst be degenerated and calcified, when operation is contraindicated. Aspiration, apart from open operation, should never be attempted owing to the risk of anaphylaxis, secondary echinococcosis and secondary bacterial infection.

Hydatid of the Lung. Next to the liver the most frequent site of echinococcosis is the lung, 10 to 15 per cent. of cysts occurring in this situation. The right lung is at least twice as frequently involved as the left. Cysts are generally subpleural, but occasionally may be deep or para-bronchial and generally contain scolices or brood capsules, but no daughters. This is important, for following rupture into a bronchus spontaneous cure more readily follows. The adventitia is thin, but owing to their high content in sodium chloride these cysts show up well with X-rays, giving a characteristic spherical shadow.

Simple Cysts (univesicular). These generally attract little attention and only one case in four is diagnosed prior to rupture or suppuration. A previous respiratory infection may be the starting point of symptoms. Pain in the chest is uncommon, but discomfort or a feeling of weight may be complained of. Cough is a common symptom and is dry at first; generally it causes little anxiety until profuse expectoration due to bronchitis, pneumonia, secondary infection or hæmoptysis supervenes. The latter complication occurs in 60 per cent. of cases and may be slight or extremely severe. Frequently a diagnosis of phthisis, new growth or aneurysm is made. In deeply seated cysts pressure on a bronchus may lead to dyspnoea and orthopnoea, while large cysts may cause an obvious bulging in the chest demonstrable by mensuration and occasionally displacement of the heart. As a rule, however, the apex beat is normal. In pulmonary cysts the outline is demonstrably circular, vocal fremitus is diminished, percussion yields a flat dull note and breath sound are absent or diminished. In cysts at the right base dullness merges into liver dullness and X-ray examination may be necessary to differentiate the condition from pleural effusion or subdiaphragmatic cysts. Congestion, collapse and infection or pericystic pulmonary tissue with corresponding physical signs may lead, especially in children, to the diagnosis of broncho-pneumonia.

Complications. Pulmonary cysts may rupture into a bronchus or into the pleura with the production of pleurisy, empyema or pneumothorax and occasionally they even implicate the pulmonary vessels and heart. **Rupture into a Bronchus.** Following this accident there is a fit of paroxysmal coughing and a saltish-tasting fluid wells up into the mouth and nose; the expectoration is frothy, usually blood-stained and may contain hydatid membrane or other elements. Often the patient gives a history of coughing up "grape skins." Death may occur from anaphylaxis or actual drowning in hydatid fluid. Other features include pain and recurrent hæmoptysis. Physical examination reveals

signs of a cavity of variable dimensions with a tympanitic or cracked-pot note on percussion, increased vocal resonance, cavernous breathing and whispered pectoriloquy. Spontaneous cure sometimes results or the cyst may suppurate, producing recurrent hæmoptysis, fever and a profuse, foetid, frothy expectoration associated with severe coughing; night sweats and rigors may also occur. Other patients present little or no fever. If long standing, wasting, anæmia and clubbing of the fingers may ensue.

Treatment. Deep para-bronchial cysts, especially if causing no inconvenience, should not be operated on as 80 per cent. undergo spontaneous cure (Dew) (68). All suppurating cysts should be opened and drained and large subpleural cysts operated on without delay; owing to the risk of bronchial flooding the patient should be so placed that the incision is made into a dependent part of the cyst cavity. Ether administered by the intratracheal route is the best anæsthetic.

Hydatid of the Brain. Primary hydatid cysts of the brain are rare in adults, but by no means infrequent in children. Usually they are single and univesicular and not infrequently associated with hepatic echinococcosis. Secondary cerebral cysts follow rupture of a cardiac cyst, are usually multiple and associated with secondary cysts in the spleen or kidney. Headache, vomiting, optic neuritis are common and localising neurological features may occur or Jacksonian epilepsy develop. In advanced cases X-ray may show osteoporosis and thinning of the cranium. With secondary cysts there may be a history suggestive of intracardiac rupture followed by a latent period before signs of increased intracranial pressure become manifest.

Treatment. Secondary cysts being multiple are inoperable, but primary cysts should be trephined without delay. The prognosis is very grave and 50 per cent. of cases die with hyperpyrexia and cardiovascular shock, the sudden release of fluid pressure resulting in cerebral oedema.

Renal Hydatid. Hydatid cysts of the kidney are generally secondary and may be located in the cortex or medulla: latency is characteristic and no symptoms may arise until quite large round cystic tumours have been produced. The general health remains good, though in large cysts an aching pain in the loin may be complained of. Rupture into the renal pelvis with passage of membrane or daughter cysts produce recurrent attacks of renal colic and intermittent hydronephrosis may develop. Transient hæmaturia may be present and the diagnosis is generally made by finding hydatid membrane, scolices or hooklets in the urine. Suppuration results in a tender renal swelling; there is persistent renal pain, frequent painful micturition and fever. The urine contains pus cells and hydatid elements.

Hymenolepis nana. This dwarf tape-worm of man, common in the Southern United States, South Europe and India, lives in the small intestine: it is probably identical with the species found in mice and rats. It measures 2.5 to 4.0 cm. in length, has 4 hemispherical suckers and a short rostellum with a single row of hooklets. The eggs contain an onchosphere and measure 30 to 45 microns in diameter. No intermediate host is required as the eggs hatch in the small intestine. The embryos penetrate the villi, develop into cercocysts, return into the lumen and become attached by their heads to other villi where they develop into mature worms (see Plate 68, 31-34, p. 1066).

Symptoms. In hyperinfection severe reflex and toxic symptoms may arise in children. These include abdominal pain, diarrhoea, insomnia, giddiness and convulsions. Eosinophilia is common. Diagnosis is made by finding ova or segments in the stools.

Treatment. Both *felix-mas* and oil of chenopodium are effective in eradicating infection.

Man has occasionally been infected with *Hymenolepis diminuta*, the common cestode parasite of the rat and mouse. Various insects, such as earwigs, rat

fleas and cockroaches serve as intermediary hosts and man becomes infected by accidentally ingesting infected insects in flour or meal.

DISEASES DUE TO NEMATODES

Strongyloidiasis. Only the female, *Strongyloides stercoralis*, is found in man and it reproduces parthenogenetically. The worms reside deep in the mucosa of the duodenum and jejunum where they lay their eggs from which the embryos escape. In a normal stool only motile embryos are found, but during diarrhoea the eggs themselves may appear; these measure 50 to 60 microns long and 30 to 34 microns broad and closely resemble ankylostome ova. On escaping from the faeces, the rhabditiform larvæ moult and may produce filariform larvæ with or without the intervention of a sexual cycle. In either case the filariform larvæ penetrate the skin or oral mucous membrane of the host and pass *via* the venous circulation to the right heart and lungs; here they break through the

FIG. 104.—Microfilariae of the blood and skin. 1. *F. loa*. 2. *F. bancrofti*. 3. *F. perstans*. 4. *O. volvulus*. 5. *Ag. streptocerca*. 6. *Mf. Malayi*, not shown, is almost identical with 1.

Species.	Insect host or vector.	Habitat of adult in man.	Habitat of embryo in man.
<i>F. bancrofti</i>	<i>Culex fatigans</i>	Lymphatic glands, ducts	Peripheral blood, night.
<i>F. ozzardi</i>	<i>Culicoides furens</i>	Mesentery	Peripheral blood, all hours.
<i>F. perstans</i>	<i>Culicoides austeni</i>	Root of mesentery	Peripheral blood, all hours.
<i>Loa loa</i>	<i>Chrysops silacea</i>	Skin and conjunctiva	Peripheral blood, day.
<i>Onchocerca volvulus</i>	<i>Simulium damnosum</i>	Subcutaneous nodules	Epidermis, especially loins.
<i>Agamofilaria streptocerca</i>	Unknown	Unknown	Epidermis, especially loins.
<i>Mf. Malayi</i>	<i>Mansonioides spp.</i>	Unknown	Peripheral blood, night.

pulmonary capillaries into the alveoli and migrate up the respiratory tract to the epiglottis and thence to the intestine where the adult female burrows into the tissues. About seventeen days elapse before the worms are mature and rhabditiform larvæ appear in the stools. *S. stercoralis* infection has a very similar geographical distribution to ankylostomiasis and not uncommonly affects man in the tropics. Enteritis may result from the activity of the gravid female worms in the small intestine where extensive erosions of the mucosa may result.

Symptoms. A primary dermatitis may result from the rhabditiform infection of the skin and pulmonary symptoms may follow a few days later associated with eosinophilia. Generally no intestinal symptoms are present, but in severe infections epigastric discomfort and diarrhoea may occur. Occult blood may appear in the stools and urticarial and oedematous rashes may be noted especially in the perianal region associated with intense pruritis due to local invasion by rhabditiform larvæ escaping in the fæces in sensitised individuals. Dermal sensitivity may be demonstrated by injecting saline extracts of strongyloid as described by Fülleborn.

Diagnosis. This is dependent on the demonstration of rhabditiform larvæ in the stools. They are easily found if the fæces be mixed with water and strained through muslin, and differ from hook-worm embryos in having a shorter pre-oesophageal buccal cavity. Where eggs occur in the stool they can be differentiated from hook-worm ova by the presence of larvæ.

Treatment. This consists in the administration of gentian violet as advocated by De Langen (69). The course consists of administering three keratin-coated pills containing $2\frac{1}{2}$ grains of this drug thrice daily after meals for a period of ten days.

Filariasis. Several species of the family *Filariidae* are known to infest man. These include *Filaria bancrofti* (*Wuchereria bancrofti*), *Filaria loa* (*Loa loa*), *Filaria perstans* (*Acanthocheilonema perstans*) and *Filaria ozzardi* (*Mansonella ozzardi*). In addition there are two larval *Filariidae*, the adults of which have not been found—*Microfilaria streptocerca* described by Macfie and Corson (70) in 1922, which is commonly present in the skin of natives of the Gold Coast, and *Microfilaria malayi* recorded by Brug (71) in 1927, occurring in the peripheral blood in the Far East (see Fig. 104 and Table).

FILARIA BANCROFTI (Plate 68, 12-15, p. 1066)

Ætiology. *F. bancrofti* is found in most tropical and subtropical countries, being specially prevalent in the West Indies, Central and Southern America, India, Southern China, the Pacific Islands, the West Coast of Africa and Queensland. The adult worms inhabit the lymphatics and periglandular lymphatic spaces where they discharge their embryos into the lymph by which means they reach the blood stream. The embryos disappear from the peripheral blood during the daytime and reappear at night, definite nocturnal periodicity being the rule. According to Lane this phenomenon is due to daily cyclic parturition on the part of the female worms, whereas Manson's view of *Microfilaria* periodicity was based on the fact that during the daytime the embryos live in the lungs and thoracic vessels, only appearing in the peripheral blood at night. The embryos measure 230 to 320 microns long and are 7.5 to 10 microns broad and are enclosed in a loose sheath which is simply the egg membrane which has become stretched during development. In the case of filariasis in the Pacific Islands no periodicity exists, and though this parasite is generally regarded as being identical with *F. bancrofti* on morphological grounds, this appears doubtful. The mosquito transmitter there is *Aëles variegatus* which bites in the daytime. The usual intermediary host for *F. bancrofti* is the *Culex fatigans* mosquito, as originally shown by Manson. The embryos are sucked up in the blood at night and undergo a series of metamorphoses in the thoracic muscles of the mosquito,

from which they finally migrate into the proboscis and are reinoculated into man during biting. After penetrating the peripheral blood-vessels they ultimately reach the lymphatics, attain sexual maturity, mate and subsequently produce *Microfilaria*. The time taken for this development within the insect vector varies from ten to forty days. Man is the only known definitive host.

Pathology. Generally filarial worms produce an eosinophilia, but little or no damage to the tissues. The embryos themselves appear to produce no pathogenic effects when circulating in the blood stream. In some patients, however, definite injury to the lymphatic system and lymphatic glands ensues which may result in filarial lymphangitis, filarial abscess, varicose groin glands, chyluria, chylocele, cystitis, lymph scrotum, chylous ascites and elephantiasis. Elephantiasis mainly affects the lower extremities, the scrotum and the vulva, while the mammary glands are occasionally affected. These pathological changes are partially the result of mechanical obstruction and partially due to the verminous adenitis and lymphangitis set up by helminthic toxin resulting in fibrosis, obstruction and lymph stasis. The rôle of the streptococcus is debatable, but probably secondary streptococcal infection engrafted on lymph stasis is the basis of the acute lymphangitis with fever. Small nodules sometimes occur in the course of the lymphatics composed of inflammatory tissue surrounding dead worms.

Symptoms. The disease is sub-clinical in the majority of patients who act merely as carriers. If there is mechanical obstruction to the lymph flow, however, filarial lymphangitis is prone to occur. Known also as elephantoid fever, this condition starts suddenly with chilliness or actual rigor, followed by a high temperature, leucocytosis, tender enlargement of the lymph glands and lymphangitis, red streaks extending up from inflammatory foci in the affected parts. Palpable nodules may be found in the course of the inflamed lymphatics. When lymphuria and chyluria are present the patient passes milky urine often mixed with blood. Cystoscopy may reveal the dilated ruptured lymphatic varix discharging milky fluid into the bladder.

Diagnosis. In sub-clinical cases the infection may be recognised by finding embryos in blood collected from 10 p.m. to 2 a.m., or eosinophilia may suggest the necessity for this examination, but once elephantiasis has developed microfilariae are rarely demonstrable. The new intradermal test, using *Dirofilaria immitis* extract as antigen, is of value in distinguishing filarial types of elephantiasis from elephantiasis nostrad. Excision of nodules in the course of the subcutaneous lymphatics and subsequent section will reveal adult worms, while X-ray examination may indicate their presence provided they have calcified.

Prevention. Prevention depends on protection from mosquito bites and the extermination of the intermediary vector.

Treatment. No specific drug treatment is known. During an attack of lymphangitis the patient must be put to bed and treated along general lines. O'Connor states that spraying filarial nodules with ethyl chloride may abort the fever if applied early in the attack. Elephantiasis is treated by the application of pressure in the form of elastic stockings or bandages, and by resting the limb in the elevated position so as to decrease lymph stasis. Surgical intervention may be necessary for certain of these elephantoid conditions and special plastic operations have recently been devised with the object of restoring the lymph flow through pedicle grafts of healthy tissue and so relieving lymphoedema (McIndoe and Gillies) (72).

***Filaria perstans* (*Acanthocheilonema perstans*)** was first discovered by Daniels in British Guiana, while Manson identified the microfilaria in the peripheral blood of negroes from the Congo. The disease exists in a considerable part of tropical Africa, including the West Coast as well as in Venezuela, Trinidad, parts of the Amazon Valley and elsewhere.

Ætiology. The adult worms are elongated, filiform nematodes, the male

measuring 45 mm. and the female 70 to 80 mm. The microfilariae vary in number in the peripheral blood, being present both day and night, and tend to concentrate in the cavities of the heart, the great arteries and the pulmonary vessels. They are smaller than *F. bancrofti* and *L. loa* embryos and measure 200×4.5 microns; they are sheathless and may be observed to undergo remarkable contractile movements during microscopic examination of the blood. The disease is transmitted by a midge, *Culicoides austeni*, and Sharp has shown its complete metamorphosis and the presence of pure larvæ in the proboscis some seven to ten days after experimental infection. *Culicoides grahamei* is also probably a vector.

Symptoms. Europeans are not commonly infected, but in Uganda and the Cameroons 90 per cent. of natives may be carriers. Pathological lesions and symptoms have not been determined with certainty, but some authorities believe lymph varix may result.

Diagnosis. This depends on demonstrating the microfilariae in the peripheral blood.

Treatment. Extermination of the intermediary host which breeds in forests, jungles and swamps would diminish the incidence of the disease. No specific treatment is known.

Filaria ozzardi (*Mansonella ozzardi*) is found in the West Indies and adjacent parts of South America. The microfilariae, which move actively in blood films, are sheathless and non-periodic. Only the female worm is known with certainty and measures 65 to 81 mm. in length. The insect vector has been shown by Buckley to be *Culicoides furens*, though Fulleborn obtained partial development in *Anopheles maculipennis*. Adult worms have been recovered from the mesentery and sub-peritoneal tissue, but there is no evidence that they are pathogenic or produce clinical symptoms. **Diagnosis.** This is made by discovering the microfilariae in blood films. No pathological reactions have yet been associated with this parasite.

LOA LOA

(Calabar Swelling).

The disease, characterised by the appearance of worms, *Loa loa*, beneath the skin and conjunctiva and the presence of fugitive swellings, is widely distributed in West Africa and is specially prevalent in the Cameroons. It is transmitted by certain species of mangrove flies, *Chrysops dimidiata* and *C. silacea*, which feed during the daytime. The microfilariae have a diurnal periodicity and are taken up into the stomach of the *Chrysops* when the fly sucks up blood from an infected patient; after breaking out of their sheaths, the microfilariae enter the muscular and connective tissues of the abdomen, undergo a series of transformations, migrate to the head and make their way through the labium during feeding about the tenth day. The fly remains infective for a period of four to five days.

Pathology. The adult worms inhabit the subcutaneous and retro-peritoneal tissues, being found under the peritoneum, pleura and pericardium as well as in the voluntary muscles and the myocardium. Klotz has described nodular fibrosis of the spleen associated with the presence of microfilariae (*Loa loa*). The calabar swellings themselves never suppurate, and result from local anaphylactoid reaction with exudation of serum and eosinophile infiltration induced by the discharge of helminthic protein into the tissues by adult worms. The swellings are unrelated either to the death of the parent worm or to the discharge of embryos into the tissues as was previously suggested.

Symptoms. The worms may be found beneath the skin in a variety of situations including the extremities, face, back, chest, breasts, penis, tongue, eyelids, conjunctivæ and the anterior chamber of the eye. There is a definite predilection for the tissues around the eye. When crossing the conjunctiva

considerable irritation and congestion may be produced accompanied by pain, swelling and dimness of vision. Considerable pain may also follow the migrations of the worms in the region of the neck of the bladder. Clinically, the worms give rise to puffy, white swellings (calabar swellings) which are generally painless and involve the subcutaneous tissue of the skin; they attain the size of a hen's egg or larger and last two or three days. The swellings may be single or multiple and recur in different parts of the body for months or even years. When occurring in the hand or fore-arm they may be associated with a sense of weakness, and where the skin is tightly bound down, as in the scalp, may cause acute discomfort or actual pain. Urticarial rashes or even asthma occasionally develop. Calabar-like swellings may be reproduced experimentally by the subcutaneous injection of filarial protein solution, and even urticaria and asthma may follow in a sensitised subject. The disease has been known to last as long as fifteen years.

Diagnosis. A history of residence in an endemic area associated with transient swellings or the appearance of worms in the vicinity of the eye is highly suggestive of this infection. Almost invariably there is a marked increase in total leucocytes and a high eosinophilia of from 10 to 60 per cent. Embryos may be demonstrable in blood collected from 10 a.m. to 2 p.m.; not infrequently, however, they are absent, especially in the early cases, and under these circumstances the complement fixation reaction, using *Dirofilaria immitis* as antigen, is invaluable as it is almost invariably positive. Intradermal sensitiveness to filarial protein is also found in the vast majority of patients harbouring *Loa loa* (73).

Prognosis. The prognosis is good, but the worms may prove troublesome for many years and swellings occur intermittently leading to temporary disability.

Treatment. No known specific treatment is available, but where it is feasible superficial worms should be extracted under local anæsthesia. In cases with urticarial and asthmatic syndrome desensitisation by injection of progressively increasing doses of a sterile saline extract of filarial protein may prove successful. Care must be taken, however, to avoid anaphylaxis, and the initial injection can with benefit be combined with adrenalin given subcutaneously.

ONCHOCERCIASIS

(1) *Onchocerca volvulus*. Infections with *Onchocerca volvulus* occur in West Africa and throughout the Congo basin, and have been recorded from Liberia, Uganda, Nigeria, the Cameroons, Senegal and French Guiana. Adults are much more commonly affected than children; it is very rare in Europeans. In 10 per cent. of cases the unsheathed embryos are demonstrable in the blood and after ingestion by the black fly, *Simulium damnosum*, undergo development in the thoracic muscles; from here they migrate to the head and on being reinoculated into the tissues of man gain access to the peripheral subcutaneous lymphatics.

Pathology. As a result of the inflammation set up by adult onchocerca worms in the subcutaneous lymphatics, cellular reaction followed by fibrosis ensues and hard, cystic tumours form, in the interstices of which male worms and embryos are found embedded in viscous material; the female worms embed themselves in tunnels in the stroma so that their removal is impossible.

Symptoms. The subcutaneous cystic nodules, over which the skin is freely movable, vary from 1 to 10 c.m. in diameter and are particularly frequent in the vicinity of the elbows, knees, ribs, iliac crest and great trochanter. Dermal lesions characterised by achromia, xeroderma and pseudo-ichthyosis may be caused by the irritation set up by embryos in the skin (Laigret) (74), and eye lesions have also recently been recorded. Some authorities have also described enlargement of the testicles, elephantiasis of the scrotum and hydrocele in

onchocerca infestation, embryos being demonstrable in the hydrocele fluid and œdematous, lymphatic tissue.

Diagnosis. The condition may need to be differentiated from dermoid cysts, fibromata, molluscum fibrosum, and juxta-articular nodes associated with syphilis and yaws. Biopsy and subsequent section of the nodule may be necessary to establish a diagnosis or embryos may be demonstrated in the aspirated fluid or in the adjacent skin.

Treatment. Excision of the nodules under novocaine anæsthesia can be carried out, especially in the vicinity of joints where they may give rise to considerable pains and discomfort.

(2) *Onchocerca cæcutiens*, which is considered by some to be the same as *O. volvulus*. In Guatemala infection with *Onchocerca cæcutiens* occurs in coffee-producing areas at a height of from 2,500 to 5,000 feet, where coffee flies abound. Three species of Simuliidæ transmit the disease—*S. metallicum*, *S. mooseri* and *S. ochraceum*. These flies bite out of doors between the hours of 8 a.m. and 6 p.m. and as many as 58·6 per cent. of the inhabitants of some districts have been found infected in Guatemala, and as many as 90 per cent. in Mexico. Children as well as adults are commonly affected. The adult worms are white opalescent nematodes, the female measuring 33·5 to 50 mm. in length and the shorter male 19 to 32 mm. The sheathless micro-filariæ are rarely if ever found in blood, and vary from 150 to 360 μ in length and 6 to 8 μ in breadth.

Pathology. Fibrous tissue nodules form as a result of irritation by the male and female onchocerca worms which become completely encapsulated in a fibrous tissue matrix; the nodules are firm, greyish-white in colour with softened centres and contain milky, gummous material in which embryos can be readily demonstrated. The microfilariæ, according to Strong (75), move about freely in the nodules, penetrate the capsule and reach the corium; similarly they invade the tissues of the eye, especially the conjunctiva, iris and cornea. An eosinophile leucocytosis is the rule, 25 to 75 per cent. of cells in the differential count being eosinophiles.

Symptoms. The clinical manifestations of American onchocerciasis include nodules, skin lesions and ocular complications. (1) *Guatemala nodules*: these are firm nodules affecting the scalp and face, measuring as a rule from 0·5 to 2·0 cm., and occasionally attaining dimensions of 5·0 c.m. (2) *Cutaneous lesions*: in the majority of cases where embryos are found in the dermis no skin lesions are found, but occasionally pruriginous and xerodermatous conditions result from their irritation. A peculiar form of erysipelas confined to the head, neck and face, known as "erisipela de la costa," has been attributed to this cause, but Strong, who has recently investigated the question, suggests it is probably secondary to streptococcal infection of the skin from scratching in a case where the corium is heavily infected with microfilariæ. (3) *Ocular lesions*: these occur both in Guatemala and South-West Mexico in about 5 per cent. of cases and consist of conjunctivitis, punctate iritis, keratitis and choroiditis; microfilariæ have been found in sections of the pericorneal conjunctiva, cornea, iris and choroid. The onset is generally insidious; conjunctival hyperæmia and small areas of opacity in the cornea may be present and photophobia complained of. Blindness commonly results.

Diagnosis. This is made by demonstrating the unsheathed microfilariæ in the milky fluid aspirated from the nodules, or in the adjacent skin, a thin piece being shaved off and teased up in saline for microscopical examination. An eosinophile leucocytosis is the rule. There is little danger to life.

Prevention. The eradication of black fly, the use of fish for the destruction of its larvæ and pupæ and of repellants are important, but specially so is the surgical removal of all nodules in the head, face and shoulder which constitute a focus for disseminating the disease.

Treatment. Removal of the nodule under novocaine anæsthesia should

be practised whenever possible. Plasmoquine, tartar emetic and foudadin are worthy of trial to remove filariæ from the skin.

DRACONTIASIS (Plate 68, 16, p. 1066)

(Guinea-worm Disease)

Guinea-worm disease is caused by *Dracunculus medinensis* (*Fuellebornius medinensis*) and is found in certain parts of Africa, India, Persia, Arabia, Turkestan and Brazil. It is specially common in countries like the Deccan in India, where step-wells are used as a source of water supply. The adult female is a thin, cord-like worm, with a rounded anterior end and recurved tail, measuring 40-80 cm. in length by 0.5-1.5 mm. in breadth. It inhabits the subcutaneous and interstitial tissues, especially of the lower limbs, and when ready to discharge its embryos secretes some toxic substance under the dermis, resulting in blister formation and ulceration. On contact with water or on cold applications to the limb, there is a reflex discharge of embryos from the prolapsed uterus which is constantly found perforating the ulcer base. After the embryos escape into water, they must be swallowed by a certain species of Cyclops which acts as the intermediary host. They burst through the stomach into the cœlom and undergo a series of developmental changes which take seven to nine days. Man becomes infected by drinking water containing infected cyclops; on reaching the human stomach these are killed by its acid secretion but the larvæ escape unharmed, invade the gut, and the gravid female appears in the subcutaneous tissues some ten to fourteen months later. The fate of the male worm is unknown.

Pathology. The blister itself is composed of (1) a layer of elevated dermis; (2) a layer of fibro-gelatinuous exudate containing entangled larvæ; and (3) a granulation tissue base with a central eschar through which the filmy uterus of the female worm protrudes; the worm lies in a tunnel in the subcutaneous tissue surrounded by a fibro-cellular layer. Three factors are responsible for the pathological lesions observed in man, namely, the female worm, the embryos, and bacteria. The toxic substances responsible for blister formation may, if absorbed, lead to anaphylactoid symptoms, while premature ejaculation of embryos into the deeper tissues may produce a sub-acute sterile abscess. Secondary bacterial invasion by such organisms as *Staphylococcus aureus*, streptococci and *Bacillus coli*, etc., cause acute abscesses, cellulitis, suppurative buboes, synovitis, arthritis, septicæmia and even death.

Symptoms. Anaphylactoid symptoms similar to those encountered in ruptured hydatid may occasionally be observed just prior to, or simultaneously with, the appearance of the vesicle; they consist of an itchy, urticarious eruption which is noted in 40 per cent. of cases, and which in certain instances may be associated with vasomotor collapse, tightness of the chest, asthmatic dyspnoea, vomiting, diarrhoea and a high eosinophilia (76). The lower extremities are involved in 86.5 per cent. of cases and less frequently the arms, trunk, buttocks and scrotum. The septic complications previously referred to may give rise to severe fever and permanent deformities due to the contracture of tendons, and fibrous ankylosis of joints may result. Rheumatic-like muscular pains and neuritis may be caused by the pressure and irritation set up by calcified worms, and cases presenting such symptoms coming from endemic areas should be X-rayed; their convoluted, moniliform shadow has been shown by Connor to be pathognomonic of guinea-worm disease. An eosinophilia accompanies dracontiasis, but on secondary bacterial infection neutrophile polymorphonuclears increase at the expense of the eosinophiles.

Diagnosis. Little difficulty is experienced in diagnosis once the worm appears at the surface of the body, but previous to that, eosinophilia and a history of residence in an endemic centre may be the only features suggestive of infection.

In doubtful cases the application of cold water or spraying the affected part with ethyl chloride will be followed by a discharge of larvæ.

Prevention. Water in step-wells and ponds becomes infected through contact with the limbs of guinea-worm cases, and measures such as the covering of wells or building cemented kerbs round ponds should be taken to prevent this. Filtering water through muslin is an effective procedure as this keeps back the cyclops.

Treatment. Urticaria and other anaphylactoid symptoms are best treated by injections of adrenalin (M x of a 1 in 1,000 solution), and if the case is seen before the blister has ruptured it should be painted with iodine and aspirated. Secondary bacterial infection almost invariably results if the worm be broken during efforts to extract it. Being elastic it retracts into the subcutaneous tissues, carrying with it the bacterial flora of the sinus and ulcer. For this reason every effort should be made to sterilise the ulcer base and sinus through which the worm protrudes before extraction is attempted. The worm may be extracted either by intermittent traction and massage, as is the custom amongst Vaidya in India, or by outlining the worm with a flesh pencil and making multiple incisions under novocaine anæsthesia. Sometimes the worm is closely convoluted on itself, and under these circumstances the whole area may be excised. A localised abscess must be treated surgically by inserting a probe through the sinus and slitting up the fibro-cellular tunnel in which the worm lies. Other septic complications require treatment as they arise. The old method of gradually extracting the worm by daily douching and winding it around a stick or match is still practised in the Orient.

TRICHINIASIS

(*Trichinosis*, *Trichinelliasis*)

Trichiniasis is a disease produced by the embryos of *Trichinella spiralis* (*Trichina spiralis*) during their migrations from the human intestine to the voluntary muscles. The disease, though rare in England, is not uncommon in America and Germany. The host reservoirs are the black and brown rat, and pigs, dogs, cats and other animals which feed on them contract the disease in this fashion. Man becomes infected by eating raw or underdone pork in which the larvæ have encysted. The cyst walls are digested by the gastric juice and the embryos are liberated, attain maturity, attach themselves to the intestinal mucosa and breed in the small intestine. The males soon die, but the impregnated females bore deeply into the villi and deposit the viviparous young in the lymphatics and possibly in the mesenteric veins. Liscard estimated that 1,500 larvæ were deposited by each female. The viviparous larvæ, which measure $100\ \mu \times 6\ \mu$, are capable of passing through the capillary bed of both the liver and lungs in their migrations, and appear in the arterial circulation from the seventh to the twenty-third day. They are deposited in muscle from the ninth day onward, and continue invading the blood stream for a period of five or six weeks, i.e., as long as the female worms survive in the gut. Throughout this period they may be demonstrated in the blood.

Pathology. During the invasive stage there may be a catarrhal or hæmorrhagic inflammation of the small intestine. Once the larvæ become deposited in the muscles, they cause local inflammatory reaction leading to the formation of a fibrous tissue capsule which is oval in shape with blunt ends; in the centre the tightly coiled larva is located. These capsules always lie with their long axis parallel to the muscle fibres. Microscopic examination shows degeneration in surrounding muscle fibre, loss of transverse striæ and an increase in the number of the nuclei. Calcification, beginning at the poles, may occur within six to nine months, and later the worms themselves sometimes become impregnated with lime salts. Encysted larvæ, however, have been known to survive thirty-one years (77). The diaphragm, intercostal and abdominal muscles and those of the tongue and larynx are particularly affected.

Symptoms. Three stages may be recognised : (1) invasive stage by the female worms ; (2) the period of larval migration ; (3) the period of larval encystment in muscle. In the first week during the *invasive stage* gastro-intestinal symptoms develop with nausea, vomiting, diarrhoea, perhaps associated with blood and mucus in the stools, and colicky abdominal pain ; lassitude, sleeplessness and depression may be present. The tongue is red and slightly furred, and later becomes dry. In the *second stage* myositis of the tongue, laryngeal and intercostal muscles and diaphragm result, and swallowing, speech and breathing become difficult. Where the muscles of the arms, legs, abdomen and jaws are involved local stiffness and pain ensue and the affected muscles become extremely painful, tender and hard to the touch. Urticaria, œdema of the face, eosinophile leucocytosis and prolonged remittent fever associated with sweating are characteristic. The electrical reactions of nerve and muscle are diminished. Trismus may occur. The implication of respiratory muscles causes shallow and interrupted breathing, making coughing, sneezing and yawning difficult, if not impossible ; this inability to cough up pulmonary secretions may lead to lung complication. Movement of the eyelids becomes painful and the power of accommodation is also temporarily lost. During the *third week* cachexia and subcutaneous œdema may develop, and in hyper-infections headache, stupor, delirium and coma supervene. Death may take place in the fourth week or earlier through toxæmia, pneumonia or bronchitis, and if the patient recovers convalescence is slow and hindered by muscular pains, muscular atrophy and persistent œdema.

Diagnosis. During the first week trichiniasis may be confused with ptomaine poisoning, enteritis or dysentery, and subsequently with rheumatic fever, typhoid or nephritis. The liability of trichiniasis to occur in groups or in several members of one family and the high eosinophilia may suggest the diagnosis ; during this stage the embryos may be demonstrated in the blood stream by the method introduced by Stäubli of mixing the blood with 10 parts of 3 per cent. acetic acid and subsequently examining the centrifuged deposit. Not infrequently this method gives positive results from the twelfth to the twentieth day. Later, biopsy on an affected muscle such as the deltoid at its insertion, the masseters, triceps and gastrocnemii, may reveal precystic or encysted larvæ ; specimens of muscle may be rapidly excised under novocaine anæsthesia. If calcified the elliptical cysts may be visible with the X-rays.

Prognosis. The mortality rate varies in different outbreaks from 1 to 30 per cent., and depends largely on the intensity of the infection. Hyper-infected patients frequently die from toxæmia or pulmonary complications, but after five weeks there is a reasonable chance of recovery.

Prevention. This depends on inspection of meat at *abattoirs* and the adequate cooking of pork. Such methods of curing pork as smoking and salting are ineffectual, but refrigeration at 5° F. for twenty days or longer is effective. Pathologists may acquire the disease during autopsy.

Treatment. No specific drugs are known, and treatment must proceed along palliative lines. Muscular pains may be treated with narcotics, aspirin, phenacetin and caffein citrate internally and belladonna applications externally.

Esophagostomiasis. *Esophagostomum apiostomum* is a nematode found in anthropoid apes in West Africa and monkeys in the Philippines and China. Some 4 per cent. of prisoners in gaols in Northern Nigeria are said to harbour the parasites. The larvæ undergo development in the wall of the intestine enclosed in fibrous nodules. As they approach maturity they erupt into the lumen, often leaving an ulcerated area, attach themselves to the mucosa and attain maturity. Here they have been occasionally mistaken for hook-worms. Clinically, colonic diarrhoea with the passage of blood and mucus may result, and occasionally peritonitis or even septicæmia ensue. Microscopic examination of the stools reveals ova resembling ankylostome eggs, and only an examination of the adult worms enables the species of helminth to be recognised. Various anthelmintics

effective for ancylostomiasis like thymol, oil of chenopodium and carbon tetrachloride cure the disease.

There is another closely related species known as *Æsphagostomum stephanostomum*, from South America; only one case has been recorded. Here nodules occurred in both the small intestine and large bowel.

ANCYLOSTOMIASIS (Plate 68, 6-11, p. 1066)

(Hook-Worm Disease. Uncinariasis)

Ancylostomiasis is caused by infection of the duodenum and jejunum with two small nematode worms, *Ancylostoma duodenale* and *Necator americanus*, which may give rise to severe microcytic, hypochromic anæmia. From an economic viewpoint ancylostomiasis is, next to malaria, the most important disease in the tropics. It has been estimated that 45 million wage earners in India alone are subject to this infection, while employers of labour in tea plantations have stated that when freed from the parasite the labourer is worth 25 to 50 per cent. more as a wage earner. *Ancylostoma brasiliense* of cats and dogs on rare occasions infects man, while that of larvæ of *Ancylostoma caninum* may cause creeping eruption.

Ætiology. *A. duodenale*, known as the "Old World hook-worm," is, according to Faust (78), the common human ancylostome of the north temperate zone of the Eastern Hemisphere; the adult males measure 8-10 mm. \times 0.4-0.5 mm. and the females 12-18 mm. \times 1 mm. The ova found in the fæces are elliptical, thin-shelled and transparent, containing two to eight segmented spherules and measuring $55-65 \mu \times 32-45 \mu$. *N. americanus*, on the other hand, is the common species in the Eastern Hemisphere south of 20 degrees north latitude, as well as the prevalent form in the Southern United States, Central and South America. It is the smaller parasite, the males measuring 7-9 mm. \times 0.3 mm. and the females 9-12 mm. \times 0.4 mm. The eggs resemble those of *A. duodenale*, measuring $64-75 \mu \times 36-40 \mu$. The adult worms of the two species differ in their buccal armature: the capsule is smaller in *N. americanus* and has an irregular border instead of the four ventral hook-like teeth characteristic of *A. duodenale*.

Life Cycle. One to two days after fæces containing ova are deposited on moist ground the rhabditiform larvæ hatch out; rarely, where patients were very constipated, they have been passed in the fæces. After moulting twice filariform larvæ emerge which may remain viable for three or even four months. When they come in contact with the human skin they bore through the tissues into the vessels and pass to the right side of the heart and lungs, subsequently travelling *viâ* the trachea, rima glottidis, œsophagus and stomach to the duodenum and jejunum—their natural habitat. Subsequently mature male and female worms develop, eggs appearing in the excreta in about five weeks. In Europe ancylostomiasis has occurred amongst miners; the heat and moisture of the mines, combined with defective sanitation, lead to infection through the naked bodies of the workers.

Pathology. The ancylostomes, which engulf the mucosa in their buccal cavity, are true blood suckers, causing local bleeding and blood loss, and at autopsy the small intestine may show petechial hæmorrhages at their points of attachment. In fatal cases the heart is dilated and its muscle shows fatty degeneration which also involves the liver and kidneys.

Symptoms. Following invasion of the skin the larvæ may produce ancylostome dermatitis, also known as "ground itch" or "cooley itch." It commences with itching following by œdema, erythema, a papular eruption and vesicle formation. The condition clears up within a fortnight unless secondary bacterial infection occurs, when pustules and furuncles result. In coolies the feet and legs are commonly affected. In Cornish miners, who call the eruption "bunches," the

hands and forearms were mainly involved. Similar eruptions may be caused by larval hook-worms of the dog and cat, which fail in man to become adult.

Symptoms may come on in six to eight weeks in severe infections; they are dependent on gastro-intestinal dysfunction and anæmia which is chlorotic in type. The Price-Jones curves show microcytosis, a decrease in the average diameter of the corpuscle and displacement to the left. The colour index is low (0.5 to 0.8) and hypochromia marked. Hypochlorhydria or achlorhydria is often present.

Whether the infection remains subclinical depends not only on the intensity of infection, but also on the response of the red marrow which undergoes compensatory erythroblastic hypertrophy. Many factors may affect this response adversely such as faulty nutrition, vitamin-deficient diets and intercurrent disease. Children fail to respond more readily than adults and women than men, and in consequence are more prone to anæmia. Those with compensated blood loss show no symptoms or anæmia; often their infection is a mild one. Partially compensated cases tire readily, develop mental lethargy, epigastric pain, discomfort, fullness of the abdomen, and flatulence. Palpitation and shortness of breath also begin to appear and "pot belly" is a common sign in children. Where the hæmopoietic response definitely fails mental and physical inertia increase; the severe case now shows a very earthy skin, a yellow discoloration of the alæ nasi and forehead, pallor of the mucous membranes and gastro-intestinal features associated with constipation or diarrhœa. Geophagia or earth-eating is not uncommon. Dyspnœa, palpitation, pulsating cervical veins, hæmic murmurs, retinal hæmorrhages, œdema of the feet and serous effusions develop; the anæmia is really severe, the red cell count varying from 700,000 to 2,000,000 cells per c.mm., the hæmoglobin from 10 to 25 per cent. and the colour index from 0.5 to 0.7. The leucocytes are normal or slightly increased in number and eosinophilia is frequent. Untreated patients may die from anæmia, cardiac failure or intercurrent disease such as pneumonia and dysentery, while in survivors detrimental defects are widespread. Mental and physical development is impeded in children and puberty delayed, while in adults the economic loss to the community cannot be computed. Mental sluggishness amongst the backward whites in the tropics and subtropics is often traceable to this cause (79).

Diagnosis. Dyspeptic disturbances, physical and mental inertia and a microcytic, hypochromic anæmia should arouse suspicion of ancylostomiasis, especially if there be an associated eosinophilia. In all cases coming from endemic areas the stools should be examined microscopically for ova—preferably by the Clayton Lane flotation method.

Prognosis. Hook-worm disease is specially serious in children, in time of famine and in those suffering from intercurrent infection like malaria, dysentery and pneumonia to which it predisposes. Appropriate treatment is almost invariably successful if not too long delayed.

Prevention. This consists in wearing good shoes and boots, in the appropriate care of fouled ground and the proper disposal of night-soil. Carriers should be treated and latrine accommodation substituted for promiscuous defæcation so common in the East. Proper sanitation should be instituted in mines.

Treatment. Several drugs with a special lethal action on ancylostomes are available. Preliminary treatment consists of a light diet, combined with saline purgatives and the administration of 30 grains of well triturated thymol in cachets, or 0.5 c.c. of oil of chenopodium at 6, 8 and 10 p.m., followed by magnesium sulphate (ounce i) at mid-day. Oil of chenopodium is of special value if there be an associated ascariasis, and some advocate its administration as a routine one week after a course of thymol. Solvents of thymol like alcohol, butter, milk, castor oil, ether, glycerine and chloroform must be avoided as they lead to excessive absorption with dizziness, headache, muscular inco-ordination,

vomiting and burning in the epigastrium resulting. The drug is contraindicated should there be fever, hepatic disease, nephritis, pulmonary or cardiac disease. Carbon-tetrachloride is given in doses of 3 c.c. in liquid form or in gelatine capsules; preliminary starvation is not advisable. An effective procedure is to combine carbon tetrachloride (3 c.c.) with oil of chenopodium (1 c.c.); a light supper but no breakfast is allowed and the combined drugs are administered at 7 a.m. followed by a saline purge at 9 a.m. At noon a light meal is permitted. During and after treatment the stools are collected and examined for ova and parasites and re-examined in a week's time. Should ova reappear, a second course of treatment with a different drug is indicated.

The anæmia is important and, in addition to eradicating infection, the patient should be given iron in large doses, *i.e.*, as ferri et ammon. cit., grains xxx., t.d.s., or four Bland's pills thrice daily after meals. In addition, where there is defective acid secretion, acid hydrochlor. dil. (B.P.) should be administered in doses of 1 drachm in diluted orange juice after meals. The diet should be nourishing, well balanced and rich in vitamins.

ASCARIASIS (Plate 68, 17-19, p. 1066)

(Round Worm)

Ætiology. In shape the adult *Ascaris lumbricoides* resembles the ordinary garden worm, the male measuring 17-25 cm. \times 3 mm. and the female 20-40 cm. \times 5 mm.; it tapers anteriorly and has a blunt conical end. The eggs are yellow and oval, possess a thick transparent shell and sometimes a mammillated covering. They measure 45-75 μ \times 35-50 μ . The unfertilised eggs are more elliptical and may be passed when only female worms are present.

Life Cycle. Ova passed in human fæces mature in the night-soil and are influenced by temperature, moisture and oxygen supply. The rhabditiform larva develops within nine to thirteen days and ova in contaminated soil may remain viable for many months or years. Upon being swallowed, the fully developed ova pass through the stomach and the rhabditiform larvæ hatch out in the intestinal juices, penetrate the intestinal wall, worm their way into the lymphatics or venules and proceed *viâ* the heart or the thoracic duct to the lungs; here they are filtered out in the capillary bed and bore their way into the alveoli. Subsequently they migrate to their normal habitat, the small intestine, *viâ* the trachea, œsophagus and stomach. The worms attain maturity some two to two and a half months after human infection, and the females begin to lay their eggs about this time.

Pathology. During migration the larvæ may produce inflammation associated with small hæmorrhages and œdema. There is pathological exudate in the respiratory passages and local eosinophilia. In hyper-infections patches of consolidation may result in the production of "ascaris pneumonia."

Symptoms. Symptoms of pulmonary involvement begin from two to five days after swallowing ascaris ova. There is fever, cough, dyspnœa and signs of consolidation resembling lobar pneumonia. Generally the temperature subsides in four or five days, but in hyper-infected patients ascaris pneumonia may prove fatal. Occasionally during migration the larvæ get into abnormal situations such as the liver, heart, muscles, kidneys and central nervous system; acute nephritis has been described associated with larvæ in the urine. Urticarial manifestations, œdema of the subcutaneous tissues and intense eosinophilia are characteristic of this stage of the disease. The adult worms may produce symptoms by toxic, reflex and mechanical means; patients sensitised to ascaris protein may develop itchy, urticarial rashes and œdema of the subcutaneous tissues, especially of the face, while in children nervousness, enuresis and even convulsions occur. Dyspepsia, flatulence, abdominal discomfort, pain and diarrhœa with or without blood, may supervene, the latter condition being known as "ascaris dysentery."

In hyper-infected cases complications are not uncommon ; they include (1) intestinal obstruction which is found in the vicinity of the ileocecal valve and caused by "balling" of ascaris worms ; (2) perforation of the intestine with peritonitis or localised abscess, with possibly sinus formation and discharge of worms through the abdominal wall ; (3) appendicitis ; (4) obstruction of the pancreatic and bile ducts leading to jaundice, cholangitis, cholecystitis or even liver abscess ; (5) œdema of the glottis due to vomited worms lodging in the trachea ; if impacted in this situation they may cause suffocation ; (6) involvement of the accessory sinuses, such as the antrum, through entry of worms during vomiting.

Diagnosis. The diagnosis of ascaris pneumonia is difficult, though it may be suspected from the associated eosinophilia and confirmed by the appearance of ova in the excreta subsequently. Intestinal ascariasis is diagnosed by the demonstration of fertilised or unfertilised eggs in the stool or the passage of adult parasites.

Prognosis. Prognosis is good except in hyper-infections where ascaris pneumonia or mechanical complications of different types may ensue.

Prevention. Undoubtedly human ascariasis is acquired from uncooked food or by contamination of the hands with infested soil. Contaminated night soil should not be used on vegetable gardens as in China, since there is no satisfactory method of sterilising it.

Treatment. Santonin, 3 to 5 grains, on consecutive or alternate days on three occasions generally proves effective. A period of preliminary starvation should precede treatment and castor oil be given as a purge. In children the dosage is proportionately less. Oil of chenopodium (1 c.c.) and carbon tetrachloride (3 c.c.) are also effective remedies ; they may be administered in combination as in ancylostomiasis. Certain complications referred to above may call for immediate surgical intervention.

Trichuriasis. This is an infection of the large bowel by the whip-worm *Trichuris trichiura* or *Trichocephalus dispar*. The adults measure 4-4.5 cm. \times 0.5 cm. The anterior two-thirds is extremely fine like a hair, but the posterior third is thicker. The eggs are brown in colour and barrel-shaped with terminal knobs, measuring $50\mu \times 23\mu$. Infection is conveyed to man through swallowing fertilised eggs in food or water contaminated with infected fæces. On reaching the cæcum the larvæ escape and attach themselves to the mucosa ; occasionally the appendix, ileum and colon are implicated (Plate 68, 4, 5, p. 1066).

Pathology. Occasionally a worm perforates the submucosa or even the peritoneal cavity. Occlusion of the lumen of the appendix may lead to appendicitis.

Symptoms. In the Orient infections are common, at least 25 per cent. of the population being infected. The condition is generally subclinical, but reflex disturbances, anæmia, urticaria and eosinophilia may occur in children.

Diagnosis depends on demonstrating the characteristic eggs in the fæces.

Prevention. Care should be taken to cleanse the hands before eating where there is a possibility of coming in contact with infected soil, while raw fruit and vegetables should be covered with boiling water for a few seconds before consumption.

Treatment. No absolutely specific treatment is available, but hexylresorcinol in a dosage of 0.6 to 1 gram in tablet form may be given on an empty stomach (Lamson) (80) with beneficial results. Oil of chenopodium is at times successful in man, and Hall found mercurochrome given by the mouth in capsules dislodged 88 per cent. of whip-worms in the dog.

Oxyuriasis. This is caused by infection with the thread- or pin-worm known as *Oxyuris vermicularis* or *Enterobius vermicularis*. These worms are more commonly encountered in women than in man, and in children than in adults. Multiple infections in members of the one family are frequent and auto-infection is common. The adults, which live in the cæcum, appendix and adjacent parts

of the large and small bowel, attach themselves to the mucosa. The male measures 3 to 5 mm. and the female 10 mm. The ova, which measure $50\mu \times 20\mu$, are thin-shelled, colourless, plano-convex in shape and contain coiled embryos; they are rarely found in the fæces. The gravid females produce intense itching in the vicinity of the anus where they often dry and burst liberating ova; on scratching the patient's finger-nails become contaminated and re-infection occurs from this source. If swallowed, the egg hatches out on reaching the duodenum and the rhabditiform larvæ are set free (Plate 68, 1-3).

Pathology. Inflammatory reactions may occur in the mucosa around the attachment of the worms, and when present in the appendix a verminous, catarrhal appendicitis may result. In the peri-anal region small hæmorrhages, subcutaneous tumours and erosions of the mucous membrane with the development of a cutaneous eczema may be produced.

Symptoms. Intestinal worms may lead to reflex symptoms, and at night after the patient has got in bed their migration out of the rectum may produce considerable discomfort and itching. Pruritus ani and eczema may develop, which may result in sleeplessness, sexual disorders and neurasthenia. Vesical irritability, frequency of micturition, mucoid secretion from the rectum and prolapsis ani may be induced, and vaginal discharges sometimes result in young girls. Occasionally the worms migrate into the stomach, œsophagus and other areas.

Diagnosis. In patients with a history of pruritus, microscopic examination of scrapings from the peri-anal region may reveal the eggs, and if the patient be examined shortly after going to bed the adult worms may be found. Not infrequently there is a mild eosinophilia.

Prognosis. The prognosis is good. Severe neuroses sometimes develop in patients with nervous instability, and systemic infection with bacteria may possibly result through the lesions induced by the worms.

Treatment. Children who are infected should sleep alone, have the nails cut short, and wear cotton gloves and sterilised pyjamas. The hands must be carefully washed after defæcation. The gravid females in the cæcum may be killed off by the administration of oil of chenopodium, santonin, thymol and filix-mas. The bowel may be washed out with a hyper-tonic saline solution (4 drachms to a pint) and followed by an enema composed of $\frac{1}{4}$ to 1 infusion of quassia, the foot of the bed being raised or, alternatively, a simple soap enema may be employed. Another effective measure consists of a preliminary bowel wash-out with bicarbonate of soda, followed by the administration of Yatren (8 ounces of 2.5 per cent. solution), which is retained up to eight hours. Unguent hydrarg. ammon. B.P. may with advantage be applied to the peri-anal region. Surgical intervention is necessary if symptoms of appendicitis exist.

Diseases due to Larvæ

2-6 MYIASIS

Myiasis results when larvæ of certain of the dipterous insects invade human tissues.

Ætiology. In the tropics, wounds and cavities discharging pus or foetid material should always be protected as there are many flies which deposit their eggs or larvæ in such a medium. Such larvæ have been recorded in the ear, nasal cavities, skin, vagina, urethra or in the intestine itself, and the fly *Wohlfartia magnifica* sometimes deposits its eggs in the conjunctival sac with serious consequences. Dermal and intestinal myiasis constitute the two chief types.

(1) **The Screw-Worm** (*Chrysomya macellaria*). This fly measures 9-10 mm. in length and is common in most parts of tropical and sub-tropical America, being distinguished from the ordinary blue bottle by three black, linear, dorsal markings on its thorax. It deposits its eggs upon discharging foul wounds. The larvæ hatch out in a few hours and when mature measure 2-3 inches in length. In

appearance they resemble a screw—hence their name. They are formed of twelve segments, each armed with a series of spines, and they burrow into and eat the tissues, producing great destruction. Once the nose is implicated the larvæ gain access to the accessory sinuses, bore their way through adjacent bones and may even penetrate the base of the skull, fatal meningitis following. When the external auditory meatus is attacked the middle ear may be destroyed.

Prevention. This consists in covering wounds and discharging orifices and sleeping under a mosquito net.

Treatment. The larvæ can generally be removed from polluted wounds by the application of antiseptics, while injections of chloroform or diluted carbolic acid are useful in nasal involvement. Operation may be necessary where sinuses are implicated.

(2) **The Mosquito-Worm** (*Ver macaque*, beef-worm) (*Dermatobia hominis* vel *cyaniventris*). The mosquito-worm is common in Central and adjacent parts of South America. It possesses a yellow head with brown eyes, a grey-coloured thorax and dark, metallic-blue abdomen. It measures 14–16 mm. in length. The larvæ are conveyed to the human skin from eggs which have become glued to the ventral surface of certain species of mosquitoes, biting flies and ticks, and after undergoing development invade the tissues *viâ* the puncture wound. A sort of boil, known as a warble, results, which contains a central opening through which the maggot respire, eliminates its black excreta and later escapes. It then proceeds to develop into a chrysalis and finally a fly. Bruce described a remarkable and sometimes fatal anaphylactic reaction in oxen and sheep infected with warble larvæ (*Hypoderma bovis* and *Oestrus ovis*) following natural trauma of the cyst. The syndrome has not been described in man, but not unlikely it occurs.

Treatment. The opening of the warble should be enlarged with a bistoury, the maggot removed and the cavity treated antiseptically. Tobacco juice is used to kill the larvæ by natives.

(3) **Ver du Cayor or Tumbu Disease.** This disease, common in Central and West Africa, is due to the larvæ of the Tumbu fly (*Cordylobia anthropophaga*). It measures 8.5–11.5 mm. in length and is yellow in colour with black spots on the abdomen. The eggs are laid on clothing or on the ground and the emerging larvæ, which possess mouth hooks, bore their way into the tissues; a pricking sensation develops and subsequently a warble or boil. These warbles affect the scalp, thighs and buttocks of children and may become inflamed and sometimes suppurate; they mature in about a fortnight and escape through the central hole by means of which their fæces were previously excreted.

Treatment. The maggot is squeezed out of the aperture which should be enlarged if necessary; the cavity is subsequently treated antiseptically.

(4) **The Congo Floor Maggot.** The adult fly (*Auchmeromyia luteola*), which is found throughout tropical parts of Africa, deposits its eggs on the floors of huts and in outhouses, and, after hatching out, the larvæ suck the blood painlessly from the tissues of people sleeping on the ground. The larvæ are about 15 mm. in length, consist of eleven segments and show considerable motility, while the adult fly is yellow in colour with longitudinal stripes on the back of the thorax; its length varies from 10–12 mm. The disease can be prevented by sleeping on raised beds.

(5) **Intestinal Myiasis.** Fly larvæ are not uncommonly observed in human fæces. Generally they are deposited after defæcation, but sometimes where the eggs are swallowed in food, larvæ may develop in the intestinal canal of man. *Fannia canicularis* accounts for most cases in Europe, but several species of other genera such as *Sarcophaga*, *Apiocæta* and *Anthomyia* may be responsible. Malaise, vomiting, diarrhœa, colicky abdominal pains, fever, rigors, headaches, vertigo and convulsions may result. The bile ducts may sometimes be invaded, with serious consequences.

Treatment. Patients should be purged with castor-oil. Thymol, filix-mas, santonin and turpentine may prove useful.

TONGUE-WORMS (Plate 71)

The adult tongue-worms, which superficially resemble tape-worms, are really degenerated, segmented arachnids which live in the nostrils or lungs of certain carnivora or snakes and deposit their eggs on vegetation; when these eggs are eaten, the larvæ encyst in the viscera of the intermediary host. Two species have been reported in man, *Linguatula serrata*, the larvæ of which encyst in the human liver; cases have been reported from Brazil and parts of Europe; the second species, known as *Porocephalus armillatus*, encyst in the mesentery, liver, lungs and other organs, and cases are not uncommon in the negroes of the Belgian Congo. Inflammation of the lungs and peritoneum may result and pulmonary signs and symptoms may follow; at autopsy larval forms are found in the peritoneal cavity. The parasites move about in the abdominal cavity over the surface of different viscera and become encysted in the liver, lungs and small intestine. X-ray in a case recently described by Low and Cordiner (81) showed the presence of peculiar shadows in the liver and other parts of the abdomen, which from their shape and size could only be cysts of *P. armillatus*; many of these presented quite clearly the crescentic appearance taken up by the nymph-forms of the parasites within the cyst during life, and which through having undergone calcification were clearly visible in the X-ray picture.

Bites and Stings

Quite apart from the transmission of filterable viruses, rickettsia bodies, and various pathogenic bacteria, protozoa and helminths, man may suffer severely in consequence of bites and stings by certain arthropods. It is essentially with the latter that the present section deals.

Insect Bites. The insects which are particularly troublesome to man from this view-point are (1) the biting midges (*Chironomidae*); (2) the buffalo gnats (*Simuliidae*); (3) the sand-flies (*Psychodidae*); (4) the mosquitoes (*Culicidae*); (5) the biting flies (*Tabanidae*); (6) the blood-sucking *Muscidae* including the stable-fly (*Stomoxys calcitrans*) and the tsetse-flies (*Glossina palpalis* and *Glossina morsitans*); (7) the blood-sucking lice (*Pediculidae*); (8) the blood-sucking bugs of the families *Cimicidae* and *Reduviidae*; (9) members of the *Hymenoptera* such as bees, ants and wasps.

Symptoms. Localised inflammation results from the irritant action of insect venoms which may occasionally exert both hæmolytic and neurotoxic effects. The clinical manifestations may be the outcome of allergic reaction in a sensitised person and under these circumstances the type of local reaction appears to depend on the site of the inoculation. If the irritant is injected into the dermis, a large urticarial wheal rapidly forms, as Boycott (82) found in the case of people sensitised to midge bites, and on reaching the deeper tissues, as in the case of the stable-fly (*Stomoxys calcitrans*), a delayed reaction associated with œdema of the subcutaneous tissues ensues. The bitten part becomes puffy and swollen, the surrounding skin is stretched over it, giving a sensation of tightness, and it may be either pallid or scarlet-red according to the reaction of the more superficial vessels. Apart from a sense of heaviness and itchiness the condition is not actually painful and swelling generally subsides in from thirty-six to seventy-two hours. In severe cases, intense itching is common and superficial vesiculation may occur. Another serious result of bites with such insects as mosquitoes and stable-flies, etc., consists of the inoculation of virulent bacteria such as streptococci into the tissues, or the introduction of specific organisms like anthrax, tetanus and gas gangrene.

With the blood-sucking *Muscids*, such as the stable-fly and tsetse-fly, imme-

diate pain results from the bite. Sand-flies bite exposed parts such as the hands, wrists, ankles and neck, particularly from sunset onwards, and give rise to almost intolerable itchiness which may recur for several days. Only the female mosquito sucks blood, some species biting painlessly, others causing much discomfort. The intensity of local reaction varies in different individuals; in susceptible people much swelling, erythema and even vesiculation may result. Blood-sucking lice commonly affect man; *Phthirus pubis*, the crab-louse, is found on the pubic hair and is often acquired during coitus; its bite may result in a considerable degree of irritation, fever and a bluish discoloration of the skin. Body lice produce erythema and itchy rose papules; vesicles may form and sometimes a bronzing of the skin, known as vagabond's disease, results; secondary sepsis may follow scratching, while head lice produce eczema of the scalp, adenitis and insomnia in children. Urticaria and itching wheals follow the bite of the ordinary bed bug, *Cimex lectularius* of temperate climates, and *C. hemiptera* of tropical climates; the latter has been found in the cork lining of sun-helmets in the tropics. The stings of bees and wasps (*Hymenoptera*) are always painful, and the intensity of local and general reaction following them is dependent on sensitisation resulting from a previous bite. Where people are bitten in the mouth, respiratory obstruction may result if the tongue and fauces be involved, while cedema of the glottis has occasionally led to death by asphyxia. In a sensitised individual profound vasomotor collapse, syncope, coma and occasionally death may follow the sting with great rapidity, while in more moderate cases one observes the development of a rapidly spreading wheal with surrounding erythema and generalised urticaria within twenty minutes. Conjunctival injection, lachrymation and chemosis follow, accompanied by headache, faintness, nausea, vomiting, vasomotor collapse with hypotension and dyspnoea of asthmatic type. Gradually the condition passes off, but next day where the bite is on a limb there may appear a large, puffy swelling in subcutaneous tissues while the surrounding skin is scarlet-red, often intensely itchy and perhaps associated with vesiculation. In extreme cases the whole limb may be greatly swollen.

Prevention. Every effort should be made to destroy insect pests, including their breeding places, while the screening of bungalows and use of mosquito nets at night are very helpful. The application of such essential oils as citronella and eucalyptus are also useful and may be applied either to the clothing or directly to the skin as ointment.

Treatment. Iodine should be applied at once in the case of bites by stable-flies and other insects likely to convey bacteria, and subsequent itching is best relieved by the application of an aqueous solution of carbolic acid (1 in 20) or an alcoholic solution of menthol (1 per cent.), or lotio calaminæ to which has been added liquor carbonis detergens and liquor plumbi subacetatis fort.

In stings by bees and wasps, pressure must not be applied to the part as otherwise the contents of the poison sac are squeezed into the tissues. The sting should be gently removed or scraped out. Subsequently, diluted liquid ammonia, powdered bicarbonate of soda or methylene blue may be applied locally for bee stings, and mild acids like vinegar for alkaline wasp stings. The appearance of anaphylactic symptoms calls for the injection of $\frac{1}{1000}$ M x of adrenalin injected subcutaneously. Sepsis is treated along usual surgical lines, while specific antisera should be immediately given in streptococcic infections associated with lymphangitis, or in anthrax, gas gangrene and tetanus.

Arachnid Bites. The arachnida include the mites, ticks, spiders and scorpions, and their bites may give rise to considerable disability.

(1) *Mites.* There is a very troublesome form of dermatitis acquired in handling such raw materials as sugar, grain, etc., known as "Grocer's itch" (*Glycyphagus domesticus*), "grain itch" (*Pediculoides ventricosus*), "water itch" in tea plantations (*Rhizoglyphus parasitius*) and "copra itch." In temperate climates the harvest mite may give rise to considerable itching and erythema.

Treatment. Gloves are the best protection against mite dermatitis. Talc powder and flowers of sulphur sprinkled in the stockings, or washing the legs with green soap or benzene are useful for the ordinary harvest mite.

(2) *Ticks*. Ticks bite man as a rule by accident. Tick paralysis in man may follow the bite of several species, including *D. venustus* and *D. andersoni*. Bites generally occur on the nape of the neck, which becomes swollen, painful and oedematous. Later, paralysis of the lower motor neuron type follows, the legs being first involved and subsequently the arms.

Treatment. In removing ticks, carbolised oil or paraffin should be applied prior to attempting extraction, as this results in withdrawal of the head and so prevents its being broken off.

(3) *Spiders*. Most spiders are not particularly dangerous to man, but some, especially *Latrodectus*, are very deadly. The *Aranæida* or true spiders possess poison glands and inject venom into their prey.

Ætiology. Spider venoms possess a predominantly neurotoxic action affecting the neuro-muscular juncture as well as the medullary centres. Guinea-pigs which are naturally bitten may die with tetanoid spasms of the muscles and bronchial spasm. Some venoms contain a hæmolysin. The red-backed spider of Australia and New Zealand (*L. hasseltii*) and the "black widow" of California (*L. mactans*) both spin their webs across the seats of dry earth closets in the country districts where sewage does not exist, and man is generally bitten on the genitals during the act of defæcation. Erysipelas, cellulitis and septicæmia, tetanus, anthrax and gangrene may follow.

Pathology. Local inflammation and even gangrene may follow the bite, but often there is little naked-eye change. At autopsy visceral congestion, petechial hæmorrhages, pulmonary oedema and with some species renal changes associated with hæmoglobinuria may be found.

Symptoms. The outstanding clinical symptoms are pain and muscular spasms of various sorts. On being bitten the patient may instantaneously develop severe pain, though in other cases its onset is delayed for one or two hours. Frequently it is intense, radiating to the limbs, testicles and the abdomen, the walls of which may be held so rigidly that an acute abdominal crisis is suspected. Vasomotor collapse follows with pallor, vomiting, sweating and low blood pressure. Dyspnoea with respiratory stridor occurs. The pupils are generally contracted and in the late stages fail to react to light. The reflexes are sluggish, weakness appears early and dysphagia and priapism may occasionally supervene. At first the temperature is subnormal, but rises later, and where secondary bacterial infection ensues, fever may persist for many days. Dilatation of the right heart, cyanosis, pulmonary oedema and coma may follow in severe cases. With some species including the "cross spider," *Epeira diadema* and *G. gasteracanthoides*, hæmoglobinuria develops.

Prognosis. The prognosis in most cases is good, but with *Latrodectus* and certain species of *Atrax*, the death rate reaches 6 per cent. or higher. In cases which recover, pain in the limbs and sleeplessness may persist for some time after acute symptoms have subsided.

Diagnosis. Where the spider is seen and there is an immediate onset of acute pain, the diagnosis is easy. When there is a latent interval and local inflammatory lesions are absent considerable difficulty may be experienced, and such divers conditions as food poisoning, cardiac failure and acute abdomen may be suspected.

Prevention. The danger of *Latrodectus* bites would be largely eliminated by careful inspection of dry earth closets before use.

Treatment. Where the extremities are bitten, immediate ligature, incision and mechanical suction should be employed, while locally iodine is a useful application to prevent secondary infection. Morphia may be necessary to alleviate pain, while laryngeal and muscular spasm may be benefited by intra-muscular

and intravenous injections of calcium gluconate (10 c.c. of a 10 per cent. solution). Circulatory failure should be combated by saline (0.9 per cent.) and glucose (5 per cent.) solutions given intravenously and by injections of coramine, pituitrin and adrenalin. Pulmonary oedema calls for the administration of atropine and immediate venesection. If convalescent serum be available it is worth a trial.

✓(4) *Scorpions*. ✓ Scorpions have a partially segmented body with strong, pincer-like pedipalps and paired poison-glands situated in the post-anal segment of the spined tail. When attacking, this is plunged forward into its prey, there being immediate ejaculation of the contents of its poison sac. Scorpions of the genus *Buthus* are well-known in the tropics, and others such as *Euscorpius italicus* and *Centrurus exilicauda* are dangerous.

Symptoms. The sting is exceedingly painful and severe toxic symptoms may follow, including nausea, vomiting, diarrhoea, sweating, cramps and fever. Trismus, stiffness of the neck, muscular paresis of different types, coma and respiratory failure may supervene. Children not infrequently die from direct toxic effects and severe sepsis may occasionally follow in adults.

Treatment. Local treatment similar to that outlined for spider bite should be instituted. The application of strong ammonia and the local injection of novocaine and adrenalin may ease pain, though morphia is at times required. A specific scorpion antivenene has been successfully prepared from horses inoculated with the contents of the poison sacs, and is widely used in Upper Egypt, where a great reduction in the mortality amongst children has been observed. The usual dose for children is 5 c.c. intravenously.

✓**Centipede Bites** (*Myriapoda*). The small centipedes in temperate climates may inject venom and cause considerable local inflammation and symptoms associated with an erysipelas-like eruption. In the tropics there is a larger centipede known as *Scolopendra gigantea*; this causes more profound local inflammation, necrosis, lymphangitis and toxic features such as generalised pains, headache, vomiting and fever. In children coma and death may follow.

Treatment follows the lines outlined for scorpion bite, but no specific antiserum is available.

Biting Leeches (*Hirudinea*). Leeches are members of the Hirudinea—a branch of the Chaetopod worms and are specially troublesome in the tropics, in leafy forests, marshy jungles, streams and rivers.

The Asiatic Land Leech (*Hæmadipea zeylanica*) measures about 1 inch in length. It occurs in India, Ceylon, Japan and the Philippines and travellers often find their socks soaked in blood at the end of a march through leech-infested forests, while people sleeping out have actually died from severe biting occurring at night. Sepsis is another danger complicating leech bite.

The Aquatic Leech (*Limnatis nilotica*) is larger and is found in the Near East. On being swallowed it fastens itself to the mucosa of the mouth, pharynx, larynx, glottis or nasal cavities of man and animals, producing severe hæmorrhage which may prove fatal unless the leech be removed. During the World War this leech caused considerable trouble in Gallipoli and Palestine.

Prevention. Gum-boots are necessary to keep leeches out, but as they may drop from the leaves of trees on to travellers in forests, a search should be made for their presence during trek. At night, if sleeping in the open, a fine mosquito net should be used. The aquatic leeches can be removed by passing drinking water through a piece of muslin or through a sieve.

Treatment. Salt or vinegar should be applied to the leeches, as these measures cause them to relinquish their hold. Traction without this will probably break off the head of the leech, leaving its suction apparatus behind and local inflammation and suppuration is liable to result. After removal tincture of iodine should be applied to the bite.

SNAKE BITE

Symptoms of snake poisoning result when a sufficient quantity of venom derived from a member of the proteroglyphous colubridæ has been inoculated into the tissues. These snakes all possess poison glands and grooved fangs (*Elapidæ*) or completely canalised fangs (*Viperidæ*) which are situated anteriorly in the upper jaw. The only snake dangerous to man with posteriorly situated fangs is the boomslang (*Dispholidus typus*).

Ætiology. Snakes are carnivorous and their venoms are merely the specialised salivary secretion of the poison gland, which is the homologue of the parotid gland of mammals. This gland is situated behind the upper jaw and the laterally compressed venom duct passes forward along the upper lip margin to open at the base of the fang which is surrounded by a fold of mucous membrane known as the *vagina dentis*. The vipers have long fangs which are completely canalised and capable of considerable forward rotation, whereas the elapine colubrids possess much shorter fangs which are grooved and possess only a limited power of elevation. It is easy to determine whether a snake is venomous or not by examining the mouth parts and ascertaining whether there are anteriorly situated fangs in the upper jaw; then by inspecting the fangs and noting whether they are grooved or canalised one can determine whether the snake belongs to the elapins or vipers respectively. The *Elapidæ* include the sea snake (*Hydrophiidæ*) which have valved nostrils and vertically flattened tails, as well as all the terrestrial elapine snakes (*Elapinae*). The *Elapinae* comprise the most deadly of all known snakes and include the king cobra (*Naia bungarus*), the spitting cobra (*Naia nigricollis*), the ordinary cobras of Asia and Africa (*Naia*), the Indian Kraits (*Bungarus*), the dreaded Mamba (*Dendraspis augusticeps*), the deadly Australian death adder (*Acanthopis antarcticus*) and tiger snake (*Notechis acutatus*), and the coral snakes (*Elaps* and *Micrurus*) of Central and South America.

The *Viperidæ* are subdivided according to the presence or absence of a loreal pit into the *Viperinae* and the *Crotalinae*. The *Viperinae* include the formidable Gaboon viper (*Bitis gabonica*), the puff adder (*Bitis arietans*), the horned viper (*Cerastes cornutus*) of Egypt, the *Echis carinatus* and the Daboia (*Vipera russellii*) of India, as well as the European vipers (*V. berus*, *V. aspis* and *V. ammodytes*). The *Crotalinae* comprise the rattlesnakes and pit vipers and include various species of *Crotalus* such as *C. horridus* and *C. adamanteus*, various species of *Agkistrodon*, the Bushmaster (*Lachesis mutus*) and the Fer-de-Lance (*Bothrops atrox*), etc.

The Mechanism of Bite. When a snake strikes it throws itself forward with great speed over a distance not generally exceeding one-third of its length and as it nears its objective the jaws swiftly open and the fangs are elevated and rotated forward. Powerful closure of the jaws drives the fangs into the tissues, and simultaneously venom is expelled under pressure through the venom duct and canalised or grooved fangs into the tissues. Fixation of the jaw is important with elapine colubrids like the cobra, and such snakes bite like a dog, often hanging on to the bitten part so that occasionally they have to be forcibly evulsed from the victim. With vipers, owing to a different arrangement of the muscles acting on the poison glands, expulsion of venom is instantaneous and independent of fixation of the jaw. So rapidly do vipers strike that the onlooker is sometimes left wondering whether the snake has actually bitten, or not.

Venom and Venom Constituents. The certainly lethal dose of venom varies with different species of snakes, as does also the venom yield. Many factors such as captivity, disease and starvation affect the yield adversely. Viperine venoms contain a toxic depressor substance producing peripheral circulatory failure, a powerful thrombase and a constituent known as hæmorrhagin, which digests the vascular endothelium and causes hæmorrhages throughout the tissues of the body.

Elapine colubrid venoms contain a neurotoxin having a curari-like action at the neuromuscular juncture which causes extensive paralysis of different muscles, including those of respiration. Hæmolysins and anti-coagulins are also present in many of these venoms. Certain species of the Australian colubrids possess venom of mixed type. The elapine colubrids generally possess an inferior inoculating apparatus, but more highly toxic venoms which kill by producing a curari-like paralysis of the respiratory muscles. The vipers, on the other hand, have an excellent biting apparatus and kill by peripheral cardio-vascular shock and internal hæmorrhage; their venom is less deadly though the local digestive action on the tissues is much more intense.

Pathology. In fatal cases of elapine colubrid bites, the mode of death is congestive, resulting from paralysis of the respiratory muscles; there is fluid blood in the vessels, dilatation of the right heart and swelling, congestion and œdema round the site of the fang punctures. In fatal viper bites multiple hæmorrhages are found in the viscera, serous and mucous membrane and the skin, but unless the inoculation has been made into a vein fluid blood is generally found in man. In the vicinity of the bite there is congestion and a gelatinous, hæmorrhagic exudate infiltrates the tissues, producing an appearance not unlike red-currant jelly. Adjacent vessels are often thrombosed, and in the later stages extensive suppuration and local gangrene is found.

Symptoms. The signs and symptoms of snake bites are dependent first on the species of snake, secondly on the quantity and site of injection of the venom, and thirdly on the body weight of the patient. Snake bite is particularly dangerous in small children.

Local Manifestations. The local lesions caused by the colubrids include numbness at the site of the bite, congestion and swelling. With the vipers there is much local pain, far greater swelling and considerable oozing of blood from the fang punctures, which are surrounded by hæmorrhage and generally separated by a distance of 1 to 3 cm. Though two is the rule, one, three or even four fang marks may result from one bite, the extra ones being produced by reserve fangs. Local suppuration and gangrene may follow, especially in viper bites, and chronic ulcers, extensive necrosis and actual gangrene of fingers, hands, feet and limbs may ensue. Some 56 per cent. of patients are bitten on the lower extremities, and the upper extremities account for another 42 per cent., body, neck and face bites being fortunately rare.

Systemic Manifestations. The interval between the bite and the appearance of systemic manifestations is determined by the quantity and nature of the venom injected and the rate of its absorption. Symptoms may appear as early as fifteen minutes; in other instances they may be delayed for many hours. The onset is characterised by nausea, faintness, vomiting, headache and signs of vasomotor collapse, with cold extremities, low blood pressure, rapid thready pulse, blanched skin and extreme prostration. Psychological shock is a real factor in snake bite, and authentic cases are reported in natives who have died from fright after having been bitten by snakes which have subsequently been proved non-poisonous.

Elapine Colubrid Bites. In elapine colubrid bites, as typified by the cobra, muscular weakness of the limbs, ataxic gait, paresis of the ocular muscles and frequency of micturition set in early; the speech becomes blurred and indistinct, and if palatal paralysis ensues a nasal quality is added to the voice. Ptosis and double vision are frequent and sensory disturbances are sometimes superadded. Ultimately, swallowing becomes difficult, the tongue swells and saliva dribbles from the mouth. The breathing, which was at first excessive and laboured, becomes shallow and slow. Cyanosis begins to appear, coma and convulsions of asphyxial origin develop, and death results from peripheral respiratory failure.

Viperine Bites. Vasomotor collapse is profound, extensive hæmorrhagic extravasations are found in the skin, blood may ooze from the gums, while

epistaxis, hæmoptysis, hæmaturia, hæmatemesis and mælena may ensue. Red blood corpuscles may appear in the urine before other hæmorrhagic phenomena become manifest.

Complications. Extensive local suppuration and gangrene frequently results from viperine bites, while with elapine bites blunting of the cough reflexes and paresis of the muscles of deglutition may terminate in septic pneumonia. In Krait bites acute ascending paralysis of the spinal cord is recorded some ten days later.

Course and Prognosis. Prognosis depends on the body weight of the patient, the quantity and quality of venom injected and the availability of specific antivenene. Most local treatment is ineffective as it is applied too late. Death may occur in from fifteen minutes to three days.

Diagnosis. Whenever possible the snake itself should be examined to determine whether it is poisonous. The clinical syndrome of blurred speech, stumbling gait and double vision has occasionally led to the suspicion of alcoholic intoxication. It is well to remember that in the Orient alleged cases of snake bite may be due to criminal poisoning.

Prevention. Much can be done by wearing strong boots with puttees or leggings, and at night lanterns or electric torches should be used to illuminate roads when walking in snake-infested country. Beds, bedding and sleeping bags should be examined, and, if camping out, a mosquito net is a safeguard.

Treatment. Two questions always arise in treatment: (1) has a lethal dose of venom been injected into the tissues? (2) has a lethal dose been absorbed into the circulation? Where large quantities of venom have been inoculated the absorption time is extremely rapid, varying from two to ten minutes with really deadly snakes, but where smaller quantities of venom have reached the tissues this period may be lengthened.

Local Treatment. The most essential procedure is the application of a ligature. A piece of rubber tubing, 1.5 cm. in diameter, makes an excellent tourniquet, or, failing this, strips of clothing may be loosely knotted around the limb and subsequently tightened by twisting with a stick as a first-aid measure. The ligature must be applied without delay around a single bone such as the arm or thigh proximal to the bite. It must be tight enough to obliterate the arterial circulation and be left in position for at least twenty minutes in the first instance; subsequently it may be loosened for a half to one minute until the limb has become flushed with blood, after which it is immediately re-applied for a similar period. Where necessary the procedure may be repeated. Early ligature decreases the dosage required to save life, and by increasing the death time sometimes enables antivenene to be given to otherwise fatal cases.

Surgical Procedures. The skin is washed with potassium permanganate solution if available, or other fluid, to remove any inspissated venom. Incision of $\frac{1}{2}$ inch in length by $\frac{1}{4}$ inch in depth over each fang mark may reveal the presence of broken fangs. It permits the subsequent application of mechanical suction by a breast-pump or Bier's suction glass, and affords an index to the efficiency of ligature, but is of doubtful value as a means of draining away venom from the fang tracks. Early free excision of the bitten tissues has more to recommend it; if ligature has been applied early, the extent and depth of the area excised varying with the species of snake implicated. Mechanical suction can subsequently be applied with benefit.

Local Injections. Different solutions are advocated, including a 1 to 5 per cent. solution of potassium permanganate or gold chloride, and the application of a ligature must precede the injection. Unfortunately necrosis and gangrene often result from these irritant chemicals and their value is doubtful.

Specific Antivenene Treatment. As a general rule, each antivenene is only antidotal to its one particular venom, and most countries where snake bite is common now produce antivenenes locally against the prevailing species of snakes.

They may be monovalent, bivalent or multivalent in type, and dosage varies with the concentration and titre. In the case of colubrid bites injections must be given intravenously, and this route is preferable in viper bites also, though concentrated antivenenes are being given intramuscularly with apparently good results in the United States. Should time and circumstances permit, the patient may be tested for hypersensitiveness to horse serum and subsequently desensitised if necessary. Antivenene should be given at the earliest possible moment, remembering that the longer it is delayed and the smaller the body weight of the patient the larger the dosage required. Children for this reason need several times the dosage which would be life-saving in an adult. Patients must be carefully watched for at least twenty-four hours after antivenene has been administered, as paralytic symptoms may reappear, requiring subsequent injections.

General Measures. The patient should be reassured, given stimulants such as black coffee and caffein citrate, and put to rest in bed with hot bottles. Strychnine and alcohol are better avoided and morphia is contra-indicated. Circulatory shock is treated by the abundant administration of warm fluids by the mouth and *per rectum*, and intravenous injections of 5 per cent. glucose where there is difficulty in swallowing. Injections of coramine, pituitrin and adrenalin may be helpful; the foot of the bed should be raised and the limbs bandaged from below upwards. Respiratory failure may be treated with coramine injections and artificial respiration and oxygen. It is important to keep the mouth and nasopharynx as free from mucus as possible, and to prevent food from entering the larynx should vomiting occur.

POISONOUS FISHES

In the tropics man is not infrequently attacked by fish, the bite or sting of which may lead to serious consequences. In some cases fish venoms such as that of *Trachinus draco* resemble snake venom in producing hæmorrhage and local necrosis when injected subcutaneously, while on intravenous injection a primary rise, followed by a fall of blood pressure with cardiac and respiratory paralysis, has been noted. A few of the more common poisonous fishes are referred to below.

(1) *Jelly Fish (Medusæ)*, of which the Portuguese man-o'-war (*Physalia pelagica*) is the best known example, may sting very severely, producing urticarial wheals, local œdema, numbness and pain extending up the limb, itching, burning and erythema; vesicular dermatitis, ulceration, and even necrosis of tissue may follow. Systemic manifestations include fever, generalised muscular pains and spasm of the abdominal muscles, lachrymation, constriction of the chest, dyspnœa and cardio-vascular shock; deaths have occasionally resulted. Probably anaphylactic shock in previously sensitised individuals is responsible for the severer manifestations.

(2) *Tropical Eels (Murænidæ)* are also dangerous, as they possess powerful, non-grooved teeth between which venom flows from poison pouches situated above the membrane of the palate. Severe local effects and cardio-vascular shock may follow the bites.

Other poisonous fish possess grooved or channelled spines or barbs connected with poison glands; the Scorpion Fish (*Scorpenidæ*), the Sting-rays (*Raii*) and the Cat-fish such as *Cridoglanis bostockii* and *Trachuris draco* may be cited as examples.

Symptoms. Locally there may be severe pain of stabbing type associated with numbness and tingling; swelling and inflammation follow, and in extreme cases purulent discharges, extensive sloughing and gangrene ensue. Amputation may be necessary. With the sting-rays, paræsthesias and paralyses of the limbs, fever, gastro-intestinal symptoms, cardiac weakness, vasomotor collapse, restlessness,

delirium and syncope may be produced. Death sometimes follows from cardiac failure or septicæmia. Tetanus has been recorded.

Treatment. The local treatment is similar to that outlined for snake bite. Morphia should be freely used for the pain. Cardio-vascular shock and respiratory failure are treated along similar lines to those already outlined. Local complications such as suppuration, abscess and gangrene require surgical treatment.

TROPICAL SKIN DISEASES

Certain skin diseases are peculiar to warm climates, while others occurring in Europe are modified by such factors as racial immunity, social customs and skin pigmentation. Thus leucoderma (vitiligo) produces great disfigurement in dark-skinned people, and may be confused with the depigmented patches of nervous leprosy. Keloid, which occasionally complicates surgical scars and burns in Europeans, is purposely produced amongst primitive peoples in connection with certain tribal customs. Keloid development, involving the ears, back, thighs and chest, are especially common amongst Central African negroes. Malignant changes are rarely observed.

✓ CHIGGER DISEASE

Chiggers are found in parts of Africa, tropical America and India, as well as in the West Indies and Madagascar. It is a common source of invalidity amongst coolies and other natives. The chigger (*Tunga penetrans*) is a reddish-brown flea, inhabiting dry, sandy soil, and readily attacks warm-blooded animals. After the female has become impregnated, she burrows obliquely into the skin and rapidly increases in size; on maturing the eggs are expelled through a small opening in the skin.

Pathology. The impregnated female causes considerable irritability and local tissue reaction; the parts become inflamed, pus forms and a pea-like elevation follows; subsequently the skin ulcerates and the chigger is expelled, leaving a small sore which may be secondarily infected with bacteria.

Symptoms. The feet are most commonly affected, since they come in contact with the ground, a favourite situation being the skin between the toes, the root of the nails and the soles. The legs, thighs, hands, face, scrotum, penis and perianal skin may also be implicated, and in severe cases hundreds of chigger sores may be present; in hyper-infection the tissues are honeycombed by the process. Severe local sepsis, septicæmia or even tetanus may follow the infection, which occasionally proves fatal.

Treatment. Where chigger is endemic the floors should be frequently swept and treated with suitable antiseptics, and walking barefooted must be avoided. The feet may be rubbed with a mixture composed of 5 drops of lysol in 1 ounce of vaseline. Careful search should be made for chiggers, which appear as black dots in the tissues; they should be removed as soon as they have fastened themselves to the skin. The orifice of entrance is enlarged with a sterilised needle, the insect enucleated and the part subsequently dressed antiseptically.

Craw-Craw (Nodular Dermatitis). The term crawl-crawl is applied to any itchy papular or pustular eruption involving the skin—particularly that of the limbs. It occurs in parts of tropical Africa, Ceylon, India, South China and the West Indies. Filarial embryos were found in the exudate by O'Neill, but they were probably *Microfilaria streptocerca*, which MacFie has since demonstrated in the skin of many West African negroes.

Symptoms. The condition originates as a papular dermatitis, the papules being hard and horny and very itchy. Scratching results in secondary infection, and a pustular dermatitis with enlargement of adjacent lymph glands may follow. Pustulation of the feet and legs is frequent.

Diagnosis. The condition must not be confused with acari dermatoses, coolie itch or scabies. No acari or other mites are demonstrable and no burrows are seen.

Treatment. Infected stockings and foot-wear should be destroyed. If pustules are present they should be opened, the crusts removed, the ulcers scraped and subsequently disinfected with 1 in 1,000 sublimate solution and then dressed with boric acid ointment on lint. Bathing in carbolic lotion (1/20) may prove beneficial.

Veldt Sore. Veldt sore is met with in South Africa, and is a chronic septic ulcerated lesion involving the exposed, hairy parts of the body. It has a wide-spread geographical distribution in the tropics and subtropics and is known as Barcoo Rot in Australia and Desert Sore in both Sinai and Mesopotamia, where it affected troops during the Great War. It is most common in hot, sandy or desert country, and occurs specially where people have to live on restricted dietaries deficient in fruit and vegetables. Streptococci, staphylococci and diphtheria bacilli have all been isolated from the lesions.

Symptoms. There is first a painful vesicle which occurs especially on the back of the hand, the fore-arm, elbows and knees. It contains a yellow fluid, and after rupturing produces a punched out, circular or oval ulcer with a tough, grey base and bluish indurated edges. It may take many months to heal, leaving a thin scar when it does so. In Sinai instances of diphtheritic paralysis of the limbs and palate were noted: the Klebs-Löffler bacillus was found in the sores, but whether it was merely a secondary invader is unknown.

Prevention. Vitamin reinforcement of the diet with orange juice, marmite, etc., is important, and abrasions should be treated antiseptically and covered. Horse manure may constitute a source of infection.

Treatment. The ulcers should be protected by sterile dressings and ammoniated or nitrate of mercury ointment applied. A high vitamin diet and iron and arsenic tonics are advisable. Anti-diphtheria serum must be given if diphtheria bacilli be present, and may be followed by dramatic cure. Auto-genous streptococcal vaccines are worthy of trial.

Tropical Ulcer (*Ulcus tropicum*; *tropical sloughing phagedæna*). This is a gangrenous, sloughing ulceration of the skin and subcutaneous tissues, resulting in the formation of chronic ulcers which are often very resistant to treatment. The disease differs from the Veldt sore in originating in damp, humid parts of the tropics—especially in the jungle. Generally there is a history of trauma, followed by the appearance of lesions in the lower limbs. It occurs especially in the debilitated and those suffering from other diseases. People of any age and either sex are susceptible, and occasionally outbreaks assume epidemic proportions amongst the coolies in tea plantations. According to Smith (83), the condition can be directly transmitted by inoculation of ulcer material from man to man. Different views are held regarding its ætiology, some suggesting deficiency disease, while others hold that a fusiform bacillus and the spirochæte, *Treponema schaudinni*, are causative. Hypocæmia is not uncommon.

Symptoms. The disease originates as a bleb containing serous or sanguineous fluid. Rupture leaves a dirty grey slough which rapidly extends into a foul, sloughing ulcer, causing considerable pain and sometimes fever. Considerable areas of tissue may be affected and deep ulceration may involve tendons, muscles, nerves, blood vessels, periosteum and even joints. The dorsum of the feet and front of the legs are most commonly affected, the hands and fore-arms occasionally. The acute stage of sloughing and spreading is followed by one of tissue equilibrium, when the growth of granulation tissue balances the area of tissue destroyed. Still later healing occurs. As a rule the ulcers persist for many months and, in extreme cases, for years; inadequate epithelial proliferation is generally responsible for delay in healing.

Diagnosis. A variety of different ulcers, such as those associated with

varicose veins, yaws, syphilis, Leishmania and fungoid granulomata of the skin, may need to be differentiated. The history of trauma and residence in a jungle area are important.

Prognosis. Most cases heal, given proper treatment and time, but occasionally in intractable cases amputation may be necessary to save life. Death occasionally results from toxæmia, inanition and septicæmia. ✓

Prevention. The use of puttees, leggings and strong boots in the jungle is advisable to prevent trauma.

Treatment. General measures include rest and a nutritious, high vitamin diet, reinforced with cod-liver oil, calcium and parathyroid extract where hypocalcæmia exists. Injections of salvarsan may prove of value. Local treatment varies with the stage of the ulcer. In the rapidly progressive stage, sloughs should be excised and antiseptic lotions of permanganate or carbolic applied. Curettage of the ulcer base and daily dressing with B.I.P.P. may have good results. Some observers have reported healing following the application of adhesive elastic strapping or elastoplast bandages. Where epithelial proliferation is slow, healing can be greatly accelerated by skin grafting.

PEMPHIGUS CONTAGIOSUS

(*Pyosis mansonii*)

This is a contagious coccal infection of the dermis, characterised by inflammation with vesicles and bullæ which ulcerate and become covered with scabs. Cultures from the lesions show *Staphylococcus aureus* and *albus*, and occasionally streptococci. European children are specially affected. The disease is common in Ceylon, Malaya and parts of Africa.

Symptoms. The initial lesion is a minute, red fleck which develops into a vesicle, a bulla, and ultimately a pemphigus-like vesicle containing fluid which at first is clear but later thick and purulent. After rupture the ulcers generally dry up and heal, not infrequently leaving pinkish, glazed scars on the skin. In children the eruption may have a widespread distribution, the whole body, except the face, being sometimes involved, but as a rule the eruption is mainly confined to the axilla and crutch. ✓

Diagnosis. The disease may need to be differentiated from impetigo contagiosa, chicken-pox, early small-pox and ring-worm.

Treatment. The avoidance of auto-infection is important. The lesions should be washed with a 1 in 1,000 solution of perchloride of mercury and a dusting powder of zinc oxide, boracic acid and starch in equal parts subsequently applied. Ung. hydrarg. ammon. is of distinct value.

TINEA

Ring-worm infections of the skin and nails abound in the tropics. The two most common ones—dhobie's itch and Hong-kong foot—are due to the *Epidermophyton inguinale*; they occur in Europe and are described elsewhere (see p. 881).

Tinea Unguium. This is a mycotic infection of the nails which is not infrequent in Europeans in the Far East, and is often associated with Tinea infection elsewhere. The nails become discoloured, lose their lustre, are brittle, grooved and pitted, while material composed of epithelial cells, tissue debris and fungus accumulate under the nails. The nail bed is definitely involved and paronychia inflammation present in varying degrees. Diagnosis is made by demonstrating *Epidermophyton inguinale* in scrapings mounted in 20 per cent. potassium hydrate solution. Treatment consists of local applications containing salicylic

acid (3 per cent.) and benzoic acid (5 per cent.). X-ray is of value, but in severe cases surgical removal of the nails may be necessary.

✓ ***Tinea Imbricata*** (Tokelau). Ring-worm affects chiefly the face, trunk and limbs, and is caused by a fungus, *Endodermophyton concentricum*, which is readily demonstrable in the epithelial scales. It occurs mainly in the Eastern Archipelago and South Pacific, being characterised by rosette-like, brown spots which give rise to flaky, tissue-paper scales, free centrally, but attached at their peripheral bases. The circular lesions are about $\frac{1}{4}$ inch in diameter, and being close-set give rise to a festooned appearance.

✓ ***Tinea Flava***. This ring-worm is common in the tropics, involves the face, neck, chest and arms, and manifests itself as a yellowish-brown, scurfy patch on the black, negroid skin. According to Castellani, the causal fungus is *Malassezia tropicalis*. There is a black variety called *Tinea nigra* which is caused by *Cladosporium mansonii*.

✓ ***Pinta*** (Caradée; *Mal del Pinto*). This is a group of dermatomycoses found in tropical America, characterised by patches of pigmentation in the skin. The disease is contagious and attacks either sex at any age. A variety of fungi are implicated, including *Penicillium*, *Aspergillus* and *Monilia*.

Symptoms. The back of the hands are first involved, with patches of pigmentation which are rough, dry, raised and vary in colour. Red, violet, white and black types are associated with different types of fungi. Gradually the condition may spread to other parts of the body, and when the scalp is involved the hair becomes white. Itchiness is marked in the skin lesions which may be of an offensive character.

Diagnosis. The patches may resemble leprosy or leucoderma; anaesthesia is not present and microscopic examination of material in 20 per cent. caustic soda reveals the fungus.

Treatment. This is the same as for ordinary ring-worm of the skin.

✓ ***Piedra*** (*Trichosporosis*). This disease occurs in British Guiana and Columbia. It is caused by the *Trichosporon giganteum*, which produces hard, gritty nodosities around the hair of the scalp.

✓ ***Creeping Eruption*** (*Larva migrans*; *Myiasis linearis*). This is a raised, linear, red eruption, which gradually extends in a sinuous fashion or as a straight line, the posterior portion fading as it progresses. It may result from the wanderings of *Gastrophilus* or other fly larvæ under the skin, but much more commonly is caused by nematode larvæ such as *Ancylostoma braziliense*, *A. canium*, *Uncinaria stenocephala* and *Gnathostoma hispidum*.

Symptoms. Sharp smarting pain and intense itching often occur at the site of the lesion, which may develop small, round, red papules or pustules.

Treatment. If the disease is due to *Gastrophilus* larvæ, surgical removal under local anaesthetic is the best treatment. For *Ancylostoma* larvæ *oilum chenopodii* diluted with three parts of castor oil should be applied locally. Spraying with ethyl chloride for two minutes at the anterior end of the larva is helpful in the case of canine ancylostomes. Blisters and pustules may be treated with mercurochrome solution or other appropriate antiseptics.

✓ ***Cercarial Dermatitis***. This is an inflammatory condition of the skin due to the passage through it of cercariae. It was first described by Cort in 1928, *Cercaria elvæ* being implicated. Taylor and Bayliss noted a similar condition in England with another species of cercariae. It may also occur as the first indication of Bilharzia infection in man.

Symptoms. These consist of itching and smarting of the skin, and the appearance of erythematous red spots, urticarial wheals and papules; occasionally pustules follow.

Treatment. This is merely palliative, consisting of the application of cooling lotions like calamine lotion combined with lead acetate, and liquor carbonis detergens to reduce itching.

TROPICAL DISEASES OF UNKNOWN ORIGIN

Ainum. This is a disease of the toes, characterised by ring-shaped constriction culminating in spontaneous amputation of the affected phalanx. The condition is found amongst adult natives and Hindoos on the West Coast of Africa, in Brazil, British Guiana, the West Indies, the Southern United States of America and India. The cause is unknown.

Pathology. The ring of fibrous tissue generally implicates the little toe. The epidermis is thickened, and there is an increase of adipose tissue associated with rarefaction and absorption of the underlying bone.

Symptoms. Clinically a groove or furrow first appears on the inner and plantar side of the base of the little toe; this gradually deepens, extending round the toe adjacent to the swelling. There is little pain, even in the early stages, and both feet may be involved. Occasionally the fourth toe is affected, but rarely the others. The fibrous tissue band may constrict to such a degree that the toe hangs on by a thin pedicle; it either drops off or is amputated by the patient.

Prognosis. The disease may last from one to ten years, but life is never endangered.

Treatment. In the early stages vertical incision through the constricting band, or, later, surgical amputation, is advisable.

✓**Big Heel** (*Endemic hypertrophy of the os calcis*). This is a peculiar hypertrophic condition of the os calcis encountered in natives on the West Coast of Africa and Formosa. Possibly it has an aetiological connection with yaws.

Symptoms. At onset there is fever associated with pain and tenderness of the heel; this gradually gets worse for the first four or five weeks and thereafter slowly diminishes; there is unilateral or bilateral swelling of the os calcis. If the condition becomes chronic, a permanent thickening of bone results.

Treatment. Surgical removal of the hypertrophic bone is indicated if enlargement be excessive and it interferes with walking.

✓**Onyalai** (*Chipola*). Onyalai is a disease of unknown origin affecting natives in Central Africa, characterised by the appearance of blood-filled vesicles implicating the mouth and other mucous membranes. Severe hæmorrhage may result when these burst.

Ætiology. Patients of any age or either sex may be affected, but young males appear particularly prone. It is found in Portuguese West Africa, in the Belgian Congo, Northern Rhodesia and East Africa. Mense suggested that it was due to poisoning by *Euphorbiaceæ*; Gilkes (84) believes it to be a vitamin deficiency.

Pathology. Hæmorrhages may involve the skin, subconjunctival tissues, alimentary tract, the serous sacs, retroperitoneal tissue, pelvis of the kidney and bladder. The inside of the cheeks, lips and palate present numerous umbilicated oval or circular vesicles of about 1 cm. diameter.

Symptoms. The condition commences with headache, vague pains in the chest, and a moderate rise of temperature, and is followed by a discharge of blood from the nose and mouth. The tongue becomes painful and swells, and there may be swelling of both parotid glands; vesicles which form inside the mouth increase to about the size of a small pea and subsequently burst, leaving a raw surface which bleeds intermittently. The breath becomes evil-smelling, the patient rapidly develops anæmia and listlessness from blood loss, and in severe cases is so weak that he cannot feed himself. In severe cases bleeding may start from the gastro-intestine, rectum or bladder, and blood appear in the stools and urine. The red cells are reduced to 500,000 to 1,000,000 per c.mm. in severe cases, and the hæmoglobin correspondingly decreased. There is a slight leucopenia, with a relative lymphocytosis of 30 to 40 per cent. The urine contains red blood corpuscles and casts.

Diagnosis. The condition has to be differentiated from viper bites, purpura hæmorrhagica, Henoch's purpura, and *Euphorbiacæ* poisoning. There are no painful swellings of the joints and the gums are not spongy, so that the condition should not be confused with scurvy.

Prognosis. The mortality rate varies from 25 to 50 per cent. Cases which show a temperature of 103° to 104° F. often do better than those with a sub-normal temperature. Relapses are not infrequent.

Treatment. The patient is put to bed, given a high vitamin diet, including fresh milk, marmite, orange juice, fruit and green vegetables, and the anæmia treated by blood transfusion, iron and arsenic. Gilkes states that calcium lactate is beneficial.

✓ **Chiufa.** This is an acute proctitis of unknown origin which starts at the anus and involves the rectum. The inflammation may involve the whole of the descending colon up to the splenic flexure. The condition affects natives in Northern Rhodesia, especially during the hot weather and rains, though it may occur at all times of the year.

Symptoms. The onset of chiufa is sudden and the disease runs an acute course which may end fatally within a few days. According to Gilkes (85), a white powdery condition appears around the anus, while in women the vulva and vagina may be implicated. This powdery appearance disappears after a few days, and the patient becomes acutely ill with a high temperature, pain in the back and neck, excessive sweating and weakness. By this time the skin round the anus appears indurated and reddened, the sphincter becomes relaxed, the anal canal dilated and gaping and throbbing pain is complained of. Constipation at this stage is the rule. As the inflammation proceeds upwards, diarrhoea and vomiting set in, the stools become mucoid and watery in type, the breath foul, and food and drink are refused. There is rapid loss of weight, urine is passed involuntarily, and the patient may die rapidly.

Diagnosis. The condition differs from the epidemic gangrenous rectitis of South America in the absence of gangrene, and is only likely to be confused with rectal schistosmiasis by those not having experience of this disease.

Treatment. No definite treatment is known, the condition having been inadequately studied. Natives apply powder containing tannic acid to the rectum, blowing it up by means of a willow reed pipe.

✓ **Chappa.** This is a peculiar affection of the joints, associated with nodules in the subcutaneous tissues which may break down and ulcerate. The disease is met with in Southern Nigerian natives, and nodules as large as a pigeon's egg may form in the subcutaneous tissues; joints may be destroyed and bones attacked.

Symptoms. At onset there is severe pain in the limbs, muscles and joints, and subsequently nodules appear which increase in size and break down and form ulcers, which may remain unhealed for years.

Diagnosis. The nodules have to be distinguished from onchocerca nodules, and the ulcers from those of tropical ulcer and yaws.

• **Treatment.** Surgical treatment includes scraping the ulcers and the application of antiseptic dressings. Salvarsan, mercury and iodides have been used without very beneficial results. The prognosis is by no means always good.

✓ **Mossy Foot.** This is an infectious papillomatous condition of the feet and legs encountered in natives inhabiting the Amazon Valley. The causative agent is not known with certainty, but some attribute it to the fungus *Phialophora verrucosa*, while others regard it as a form of skin tuberculosis. It has been described in Brazil, Honduras, Costa Rica and Guatemala. The disease is infective and may spread by auto-inoculation from one part to another.

Pathology. Granulomatous, warty masses composed of vascular tissue are found on the feet and legs; there may be yellow crusts, but sinuses do not occur.

Symptoms. The disease commences as a vesicle on the dorsum of the foot, extending upwards until the whole of its surface, as well as the skin of the leg, is covered with vascular, warty lesions, which are very painful. The sole of the foot is not implicated. Sometimes it attacks people with elephantoid legs. Many years may elapse before the disease is fully developed.

Diagnosis. Verruga nodules, Madura foot and ulcers of tertiary yaws and syphilis may need to be differentiated.

Treatment. This consists in excision by means of a cautery; X-ray treatment has been used in some instances with success.

ULCERATING GRANULOMA

(*Granuloma venereum*, *Granuloma inguinale*. *Ulcerating Granuloma of the Pudenda*. *Serpiginous Ulceration of the Genitals*)

A venereal disease occurring in many parts of the tropics characterised by a chronic progressive ulceration involving the genitals, perineum and groins of both sexes.

Ætiology. The disease was first noted in British Guiana and the West Indies, but is now known to occur in Porto Rico, Brazil, Northern and Central Africa, India, China, the Pacific Islands and Northern and Central Australia. After puberty both sexes are affected, and natives races as well as Europeans are susceptible. Several different ætiological agents have been implicated, including spirochætes, a capsulated organism—the *Microbacterium capsulatum granulomæ*—present in plasma cells and recorded by Flu as related to the Friedlander group, and an oval bacillus described by Donovan and others, contained in endothelial cells which is present in scrapings from the ulceration. Probably none of these organisms is of ætiological significance. The disease is definitely venereal and contracted during coitus.

Pathology. From the pathological viewpoint the disease is allied to the infective granulomata; microscopic section reveals vascular tissue containing an abundance of round and plasma cells and clumps of intracellular bacilli. The older areas undergo fibrosis as the active ulceration extends peripherally without involving the lymphatics.

Symptoms. The disease begins on the penis or labia as a vesicle or flat papule; the covering epithelium undergoes desquamation, exposing granulation tissue which bleeds readily and soon becomes covered by a creamy, offensive pus. Where the glans is involved a fungating growth resembling epithelioma may form. The ulcerative process extends by direct continuity to the groins and thighs, while in the female the vagina, perineum and peri-anal skin may also be involved and recto-vaginal fistula result. In the skin lesions cicatrisation occurs in older areas as the ulceration slowly extends peripherally, but healing never follows in mucous membranes, where the extension takes place much more rapidly. Similar ulceration has been stated to involve the face, neck and mouth. Outstanding clinical features are the chronic nature of the ulcerative process, the tendency to scarring in the skin, the absence of lymphatic involvement, the mild degree of pain and discomfort complained of and the satisfactory state of the general health. Complications include urethral stricture, septic cystitis, pyelitis and vesico-vaginal fistulæ.

Diagnosis. Syphilis or tubercular ulceration may be suspected or lupus vulgaris simulated, and when the glans penis be involved a fungating epithelioma may be the diagnosis until biopsy reveals a different pathology.

Prognosis. The disease naturally runs a very chronic course extending over many years and often lasting for life. Where the mucous membranes are involved progress is more rapid. Modern treatment has greatly improved the outlook.

Prevention consists in the avoidance of sexual connection with infected people.

Treatment. In the early stage where the ulceration is still superficial surgical incision of the ulcerated area, preferably with the electric cautery, results in cure. Where the ulceration has extended more deeply surgical intervention may be impractical, and here intensive treatment with tartar emetic should be given intravenously as in schistosomiasis; a total amount of 60 grammes is generally necessary, though in intractable cases more than twice this dosage may need to be administered. Non-specific protein therapy may also stimulate healing and is worth a trial in sluggish cases; the best procedure is to give T.A.B. vaccine intravenously, commencing with 50,000,000 per c.mm. and gradually increasing to 300,000,000 per c.mm. in a series of six injections given at three or four daily intervals.
